Abstract

We study social media's distinctive model of content production. Unlike legacy media outlets, social media platforms do not professionally produce content designed ex-ante to engage viewers; instead, they harvest content created for nonpecuniary reasons by large numbers of amateur users. The resulting scale and diversity of platforms' content libraries, combined with their ability to test content on subsets of users, facilitates granular ex-post discovery of pieces that engage each viewer. We develop a model of this process and show that it leads the content consumed in equilibrium to depend on viewer preferences (demand) but also on creator preferences (supply), because the production scale powering platforms' discovery concentrates where creators are eager to produce. Collecting new data on Instagram, TikTok, and X/Twitter, we show that viewers' feeds are dominated by amateur creators who produce envy-provoking "lifestyle" and partisan political content in pursuit of social status and expressive satisfaction. To disentangle supply and demand, we experimentally generate shifters on both sides of the market by manipulating viewers' feeds and eliciting creators' incentivized preferences while paying them to produce content. On the demand side, pieces of lifestyle and partisan content are less likely to highly engage viewers than more benign entertainment. But these content types enjoy enormous supply-driven production scale. This enables platforms to cherry-pick the minority of such pieces viewers find more engaging than the marginal piece of entertainment. Estimating our model using the experimental variation, we calculate that supply-side preferences account for one- to two-thirds of the prevalence of envy-provoking and partisan content in viewers' feeds.

1 Introduction

Over the past twenty years, social media platforms have gradually displaced legacy media outlets to become many users' primary source of news and entertainment. Critics allege that by serving users content provoking political grievances and personal insecurities, and fragmenting their attention spans with short-form feeds, these platforms drive recent declines in political cohesion, mental wellbeing, and academic achievement.[1]

The common view in research and commentary is that these problems originate on the demand side.[2] In the standard account, social media algorithms excel at predicting what will engage users, and outrage and envy are highly engaging; moreover, platforms keep users compulsively scrolling by designing short-form feeds that, like slot machines, offer a stream of variable and unpredictable rewards. On this view, what differentiates social from legacy media is superior technology for identifying and exploiting latent demand.

This paper develops a new and complementary way of thinking about what distinguishes social from legacy media, focused on social media's unique *supply* side. Unlike legacy media outlets, social media platforms do not professionally produce material designed ex-ante to cater to what viewers like to *watch*; instead, they harvest material that amateur users like to *create* in pursuit of social status, expressive satisfaction, or creative fulfillment. This lets them cheaply accumulate enormous libraries of content. They then sift through these libraries by explicitly or implicitly testing pieces of content on subsets of users, thereby converting massive supply-side scale into granular ex-post *discovery* of pieces that turn out to resonate with viewers.

This business model has two implications. First, because the production scale fueling platforms' discovery concentrates selectively in the regions of the content space where creators are most eager to produce, creators' supply-side preferences can end up shaping what viewers consume. For example, the expressive satisfaction that politically extreme users derive from posting partisan content, or the social status that attractive users gain from posting self-centered content, can lead to patterns of production that fill viewers' feeds with polarization- or envy-provoking material. Second, to enable maximally granular ex-post experimentation and discovery, the business model favors media formats broken into small units, such as short posts or videos.

In this paper, we study the business model of social media in three steps. First, we develop a framework microfounding the contrasting business models of legacy and social media. We characterize how social media's model leads supply- and demand-side preferences to jointly determine equilibrium consumption. Second, we collect new data on the production and consumption of social media content. We document a sequence of facts confirming assumptions and predictions of our model and showing that nonpecuniary supply-side preferences may drive the equilibrium prevalence of status-oriented "lifestyle" and partisan political content. Third, we conduct supply- and demand-side experiments to generate the variation required to decompose equilibrium consumption of these content types into supply- and demand-driven components.

Conceptual Framework. Our framework features three groups of agents: creators who produce content in pursuit of pecuniary and nonpecuniary rewards; viewers with heterogeneous tastes; and a profit-maximizing outlet that pays creators to produce, distributes produced content to viewers, and extracts viewer surplus.

We assume content production is a noisy process (Goldman, 1983). A content "type" is distinguished by a few features such as style, slant, topic, or production value. Pieces of a given type have a baseline appeal

[1] See Allcott et al. (2020); Levy (2021); Braghieri et al. (2022); Haidt (2024); Bursztyn et al. (2025); *People v. TikTok Inc.* (2024).
[2] See Eyal (2014); Allcott et al. (2022); Beknazar-Yuzbashev et al. (2024); Bao (2026); Solheim and Wang (2026); Bolte et al. (2026).

reflecting viewers' taste for these distinguishing features. When created, a piece additionally draws a quality shock and a vector of taste shocks for each viewer, reflecting other features that emerge serendipitously during production, such as comic timing or visual or narrative resonance.

The quality and taste shocks are realized only once a piece is produced, and even then are not automatically visible to the outlet. We assume that *legacy* outlets face technological constraints on testing and distribution that prevent them from measuring and acting on these shocks when disseminating content (Waldfogel, 2019). They therefore optimally procure and widely distribute a few pieces of content with high ex-ante appeal.

The Internet relaxes these constraints and births a new business model premised on procuring large numbers of pieces and testing them on subsets of viewers to measure their shock realizations before distributing them. This "discovery" step facilitates ex-post cherry-picking of pieces with high quality shocks and personalized distribution of pieces to viewers based on taste shocks. It increases the returns to production *scale* and thereby induces a shift towards content types that are cheap to procure in large quantities by virtue of being easy or satisfying to produce. It also rewards disaggregation of content into the smallest units over which shocks are realized. The result is the rise of outlets harvesting and distributing short "social" posts.

In this new business model, equilibrium consumption of a content type depends on *demand*—its distribution of appeal to viewers—and *supply*—creators' nonpecuniary taste for producing it. Even if a content type has lower average appeal, the more it is produced, the more opportunities there are for high quality or taste shock draws to carry pieces into viewers' feeds.

For example, consider a viewer who seeks out political news or commentary and *ceteris paribus* prefers ideologically moderate content. If moderate users dislike arguing about politics online, they will produce only a thin pool of political content, limiting a platform's ability to cherry-pick moderate posts that this viewer will find particularly interesting or amusing. If, meanwhile, political extremists enjoy posting constantly about politics, the sheer scale of their output will throw up more unusually appealing outliers on dimensions other than slant. Our viewer may hence find herself with a feed full of extreme posts so much more interesting or amusing than the best available moderate posts that this overcomes her mild distaste for extremity.

Comparative Statics. The influence of supply-side tastes on equilibrium consumption is mediated by two factors. First, supply-side tastes matter more when the variances of the quality and taste shocks are high. With high-variance shocks, the scale at which a content type is produced—and therefore the number of shock draws it generates—becomes more important than its baseline appeal in carrying it into viewers' feeds.

A different way to put this is as follows. The example we gave above assumed that content creation is dominated by intrinsically motivated amateurs rather than by professionals. It also assumed *scarcity* of appealing content: our viewer saw extreme content due to a *lack* of comparably amusing moderate content.

High-variance shocks endogenously create these conditions. Intuitively, such shocks represent viewer preferences that depend on many difficult-to-target dimensions of content other than, e.g., slant. If viewer preferences are predictable and low-dimensional, professional creators enter and supply abundant content catering to those preferences. In contrast, unpredictable and high-dimensional preferences make it difficult to consistently appeal to viewers—preventing professionalization and dispersing production over many expressively motivated amateurs—and create local scarcity of content near viewers' ideal points.

Second, supply-side tastes matter more when low pecuniary rewards or concave nonpecuniary satisfaction from attention lead creators to care less about viewership on the margin. The less creators value marginal increases in viewership, the more they indulge their own tastes rather than catering to viewers'.

Observational Data. To test our model's predictions, we collect four new datasets spanning consumption and production on social media. First, we pay 383 young Americans to download their personal data on Instagram, TikTok, and YouTube and install an extension recording their X/Twitter feeds, yielding second-by-second histories of the posts they consume on these platforms. We scrape and classify the contents of these posts and scrape information about their creators. Second, we use TikTok's API to construct a representative sample of the videos *produced* on TikTok. Third, we contact and survey 301 of the creators appearing in our data. Fourth, we survey 3,490 users of these platforms and scrape their accounts, to measure selection into posting. For data quality reasons, we focus on TikTok and discuss results for other platforms below.

Observational Evidence on Amateur Production and Scarcity. We begin by testing our model's prediction that high-variance ex-post quality and taste shocks create room for supply-side forces to matter by dispersing and deprofessionalizing production and creating local scarcity of the content each viewer finds most appealing.

We show that ex-post video-to-video variation in appeal is much larger than ex-ante stable variation in appeal across creators. Only 6% of the typical TikTok viewer's feed comes from creators she sees consistently enough to see at least once per 1,000 videos. The modal video in her feed is a one-off hit from a small creator she sees once and never again, which receives hundreds of times more views than its creator's median.

This ex-post variance deprofessionalizes production. Large professional creators exist, but they are vastly outnumbered by a long tail of small creators who do not earn money and report posting for expressive reasons. Since successful content emerges in a seemingly random and fairly even way from across the distribution of production, about two-thirds of the content in viewers' feeds originates from the long tail of amateurs.

The sparse and unpredictable origins of the most appealing content also create scarcity of such content. Although viewers predictably engage about 25% less with "stale" content posted more than a week ago, after 20 minutes of scrolling, half of a viewer's feed is stale, indicating a paucity of engaging fresh material. Greater scarcity increases the rate at which exceptional posts from disliked content types enter viewers' feeds.

Observational Evidence on Lifestyle and Partisan Content. The preceding facts show that the conditions necessary for supply-side forces to influence consumption are satisfied. We next zoom in on specific supply-side forces. We show that the small creators driving production are selected on self-reported political extremity and attractiveness. These characteristics respectively predict posting of partisan political content and self-centered "lifestyle" content, which together make up half of production and a third of viewers' feeds.

The production of lifestyle and partisan content does not appear to reflect attempted catering to viewer demand. We exploit the fact that TikTok's Creator Rewards program, which pays creators per view they receive, applies only to videos at least a minute long. Financially motivated creators chasing viewership should therefore bunch their videos at and above 60 seconds. We show that after Creator Rewards is introduced in 2023 (but not before), crossing from 59 to 60 seconds increases the prevalence of *entertainment* content by 40% and *reduces* the prevalence of lifestyle content by 30%. It does not change the partisanship of political content. This suggests lifestyle and partisan content are not produced strategically to stir up engagement.

Disentangling Supply and Demand. While directionally indicative of the importance of supply-side preferences, the observational evidence described above does not provide the variation necessary to estimate the parameters of our model and thereby decompose equilibrium consumption of lifestyle and partisan content into supply- and demand-driven components. To generate this variation, we conduct two experiments.

On the demand side, we wish to identify each content type's baseline appeal and the distributions of its quality and taste shocks. Identification problems arise from selection of the pieces we see viewers engaging with observationally. Pieces creators choose to produce are selected on the predictable component of quality heterogeneity. Pieces in viewers' feeds are further selected on the realizations of the ex-post quality and taste shocks. Creator preferences influence the extent of this selection by changing the cutoff of predictable quality above which creators are willing to produce. Solving these problems requires randomly sampling from the latent distribution of potential videos and measuring viewers' engagement with these sampled videos.

On the supply side, we wish to separate creators' intrinsic tastes over content types from their valuation of, and expectations about, viewership. The following example illustrates the resulting identification problem. In one world, creators care primarily about how many views they receive. They therefore produce content type A over type B because they expect A to attract more views. In another world, this happens because creators simply enjoy producing content type A and dislike producing content type B. We cannot distinguish these worlds observationally because we do not see the latent viewership of content that is *not* produced in equilibrium, and because we do not know whether the content that *is* produced would still be produced if it received fewer views. Solving these problems requires eliciting the viewership of videos that are not produced in equilibrium and measuring creators' valuation of viewership.

Demand Experiment. For our demand-side experiment, we build a phone-based TikTok clone and populate it with videos randomly sampled from all of TikTok, plus videos whose creation was induced by our supply-side experiment. We recruit 586 TikTok users to scroll through it, measure their engagement behavior, and use it to estimate a parametric model of the distribution of viewer utility from different content types.

We have three results. First, lifestyle content faces the lowest demand of the types we study. For example, lifestyle videos are about 5 percentage points, or 25%, less likely than entertainment videos to be watched for at least ten seconds. Second, partisan political content enjoys a small demand premium over nonpartisan content.[3] Third, consistent with across-type variation in baseline appeal being small relative to the residual within-type variance of quality and taste shocks, engagement differences across content types are small and viewers enjoy a substantial minority of videos of each type.[4]

Overall, these results show that neither lifestyle nor partisan content enjoys a substantial demand premium, suggesting their considerable supply advantage may reflect nonpecuniary creator preferences rather than attempts to chase demand. Moreover, residual viewer preference dispersion appears high enough to make consumption rates very sensitive to production rates. For example, if lifestyle videos are on average 25% less likely to highly engage viewer i than entertainment videos, a pool of lifestyle videos only needs to be

[3] Observationally we found no sign of a partisanship demand premium, in contrast to the slight premium in our experiment. This is perhaps because, as we show, the general population of TikTok users is more moderate than the participants in our experiment. We therefore view our experimental estimates as an upper bound on the demand premium enjoyed by partisan content.

[4] To distinguish preference dispersion from noisy behavior, we ask participants at the end to choose between pairs of videos they saw, and use concordance of their choices with their prior engagement to estimate and purge behavioral noise; this barely affects results.

33% larger than a pool of entertainment videos in order to contain more videos that will highly engage i.

Supply Experiment. To study creator preferences, we recruit 979 TikTok creators and offer to pay them to post different types of content while also offering interventions to increase their viewership. These offers allow us to elicit their incentivized willingness to make posts of each type; their incentivized expectations about viewership; and their incentivized marginal valuation of viewership. We use these objects to back out the creator utility parameters in our model. The offers we extend induce the creation of 106 TikTok posts.

We find substantial variation in creators' willingness to post different content types, but almost none of it is explained by expectations about demand. Creators expect only slightly lower viewership for content types they are unwilling to post, and in fact receive slightly *higher* viewership when paid to post them. Moreover, although creators value attention, their *marginal* valuation of viewership is low, reflecting sharp concavity of utility from attention.[5] Instead, 82% of creators say they create certain content types because they find them easy and satisfying to create, and not others because supplying them would be difficult or uncomfortable.

These results derive from complex willingness-to-pay objects, but are robust to a much simpler design that varies whether we ask about creators' binary willingness to *post* a piece or shut down expectations about demand by asking their willingness to *privately create* a piece to be shown to a few other participants.

Overall, our results suggest that production of lifestyle and partisan content by attractive and politically extreme users is driven by supply-side expressive motives rather than attempted catering to demand.

Supply-Demand Decomposition. We combine the parameter estimates from our viewer and creator experiments and use our model to analyze counterfactuals. We have two sources of demand-side data—our viewership experiment, and viewership expectations from our creator experiment—and results are robust to using either. We find that equalizing creators' intrinsic preferences for producing different content types would reduce equilibrium consumption of both lifestyle and partisan political content by one- to two-thirds.

Cross-Platform Comparisons. For data quality reasons, our experiments and descriptive results focus on TikTok. We show that the descriptive patterns we document replicate on Instagram and X/Twitter. In contrast, YouTube looks much closer to television than to the other social media platforms: it pays creators more generously, creators are more professionalized, and viewership is more stable. Perhaps commensurately, participants in our surveys express much more positive views of YouTube than of the other platforms.

Welfare Implications. We close by discussing welfare implications. Our framework predicts social media viewers may be matched to content they find aversive on certain creator-driven dimensions, but this should be compensated by greater appeal on other dimensions, captured by the quality and taste shocks. To test this, we pay the participants providing their viewership histories to first spend a week using an iPhone app we built that pings them while they are on social media and asks how they are feeling. We link their responses to their contemporaneous viewing and exploit high-frequency variation in the content appearing in their feeds for identification. We find results consistent with our predictions: political and attractive lifestyle content predictably trigger negative emotions, but participants also find these videos entertaining and interesting, rarely report regretting having watched them, and do not express a particular desire to block their creators.

[5]This finding is consistent with prior work on social media (Srinivasan, 2024), and with a range of facts about how creators derive utility from attention, sourced from 105 AI-conducted open-ended 15-minute interviews we collect from creators in our sample.

However, we remain agnostic on welfare. The outcomes we collect are too narrow and short-run to support confident conclusions. Our model allows the shift from legacy to social media to *reduce* welfare if particular internalities or externalities load on dimensions of content driven by creator preferences—for example, if viewers underestimate the long-run psychological effects of repeated exposure to unfavorable social comparisons, or if toxic news diets have negative externalities for democracy.

Related Literature. We contribute to two literatures. The first studies the political economy of media. The canonical question in this literature, reaching back to Mullainathan and Shleifer (2005), Gentzkow and Shapiro (2006, 2010), and Besley and Prat (2006), is whether features of equilibrium media content (such as slant) reflect supply or demand.[6]

Because most papers in this literature study legacy media, the supply-side distortions they look for—including editorial pressure from wealthy owners or repressive governments—are examples of *top-down* elite capture. We study a different kind of supply-side distortion: *bottom-up* capture of media by the masses of people willing to spend much of their time posting online, who may be *negatively* selected on factors like institutional enfranchisement and satisfaction with the status quo. The Internet-precipitated transition from media susceptible to top-down pressures to those susceptible to bottom-up pressures offers one lens through which to interpret political trends over the last 20 years in liberal democracies, including the rise of populist parties and fringe ideologies and declining popularity of mainstream parties and institutions.

Second, a growing literature both within and outside of economics examines the relationship between social media and political outcomes (reviewed by Zhuravskaya et al., 2020; Aridor et al., 2024); a similarly large and interdisciplinary literature examines the relationship between social media and mental health and wellbeing (Allcott et al., 2020; Braghieri et al., 2022; Bursztyn et al., 2025; Beknazar-Yuzbashev et al., 2026). These two literatures have mostly proceeded independently and emphasized different and almost exclusively demand-side mechanisms. These include political homophily (Allcott and Gentzkow, 2017; Levy, 2021; Müller and Schwarz, 2021; Acemoglu et al., 2024b; Braghieri et al., 2024), self-control problems (Allcott et al., 2022; Beknazar-Yuzbashev et al., 2024; Bao, 2026; Solheim and Wang, 2026; Bolte et al., 2026), other consumption frictions (Acemoglu et al., 2024a; Braghieri et al., 2026; Moehring, 2026), and strategic complementarities that create collective consumption traps (Bursztyn et al., 2025, 2026).

Our primary contribution is to provide a new theory of social media centering its distinctive *supply* side. Authors in the literature have pointed out social media's unique amateur production model (Zhuravskaya et al., 2020; Aridor et al., 2024) and noted its upsides as a potential "liberation technology" empowering repressed populations (Enikolopov et al., 2020; Fergusson and Molina, 2019) and downsides as a source of toxicity or misinformation potentially necessitating content moderation (Guriev et al., 2026; Beknazar-Yuzbashev et al., 2025a). Other authors have studied the sensitivity of production to attention (Srinivasan, 2024; Filippas et al., 2026; Balbuzanov et al., 2025), political selection into production (Bail, 2021; Schulz et al., 2026), and the effects of exposure to user comments (Donati and Song, 2026).

But the literature lacks a unified account of the social media production model's origins, purpose, and

[6]For reviews, see Gentzkow et al. (2015) and Puglisi and Snyder (2015). Other papers include Baron (2006); Duggan and Martinelli (2011); Durante and Knight (2012); Martin and Yurukoglu (2017); Qin et al. (2018); Martin and McCrain (2019); Beattie et al. (2021); Szeidl and Szucs (2021); Angelucci et al. (2024); Boxell et al. (2026); Cagé et al. (2025); Noy and Rao (2026).

implications. We provide a comprehensive account of social media's business model as arising from a *complementarity* between production scale enabled by reliance on user-generated content and technological advantages that facilitate cherry-picking from large content pools. This lets us do three things. First, we clarify and microfound the key difference between social and legacy media. Second, we trace out one implication of this difference: an increase in the influence of creators' supply-side preferences on equilibrium content consumption. Third, we show how this implication could help tie together the political and mental health effects of social media via a common supply-side mechanism: self-selection into production by creators prone to causing negative reactions in viewers.

Finally, as we discuss later, our comparison of social and legacy media extends the insights of a small literature studying the effects of the Internet on legacy entertainment industries (Brynjolfsson et al., 2003; Waldfogel, 2016, 2017, 2019; Aguiar and Waldfogel, 2018).

Roadmap. Section 2 develops our model of social media and compares social to legacy media. Section 3 compiles observational evidence on social media corroborating our model's predictions and motivating the importance of nonpecuniary supply-side preferences. Section 4 uses demand- and supply-side experiments to estimate the parameters of our model and decompose the equilibrium prevalence of envy-provoking "lifestyle" content and partisan political content into supply- versus demand-driven components. Section 5 provides tentative evidence on welfare implications. Section 6 concludes.

2 Conceptual Framework

In this section, we write a simple model of social media and use it to analyze how supply- and demand-side preferences interact to determine equilibrium content consumption. We then compare social to legacy media, analyzing how they differ technologically and what this implies for the types of content they favor.

2.1 A model of social media platforms

Agents. The model involves a finite set of viewers $i \in I$, a continuum of potential creators $j \in J$, and a platform intermediating between creators and viewers.

Viewer utility. Pieces of content belong to "types" $k = 1, \ldots, K$. Viewer i's utility from post p of type k is:

$$u_{ip} = m_k + \widetilde{m}_{ik} + q_p + e_{ip} \tag{1}$$

Here, m_k is viewers' average taste for type k. $\widetilde{m}_{ik}$ is individual i's personal taste for type k relative to other viewers, and has mean zero across viewers. q_p is piece p's vertical quality, and e_{ip} is its idiosyncratic appeal to viewer i. q_p and $\{e_{ip}\}_{i \in I}$ are drawn upon piece p's creation from a creator-specific joint distribution and average to zero across potential pieces of each type.

A viewer's utility from post p in a sequence is $u_{ip} - \gamma h_{ik(p)}$, where $h_{ik(p)}$ is the share of posts in the sequence of p's type and $\gamma \geq 0$ is a parameter capturing diminishing marginal utility from a content type.

Interpretation. We interpret content "types" as representing cells in a coarse partition of an underlying high-dimensional characteristic space. Across types, pieces differ systematically from each other on a few dimensions such as topic or style, creating variation in m_k. Pieces *within* a given type also differ from each

other on many residual dimensions, creating variation in q_p, e_{ip}. "High-dimensional" preferences cover many features other than the few captured by variation in type, resulting in high variances of q_p and e_{ip}.

Creator utility. If creator j produces a unit of content of type k which receives v views, their payoff is:

$$\pi_{jk} = \mu_k + \widetilde{\mu}_{jk} + \beta v^{\rho} + wv \tag{2}$$

Here, μ_k represents creators' average taste for producing pieces of type k, and $\widetilde{\mu}_{jk}$ is a creator-specific deviation. βv^{ρ}, where $\beta \geq 0$ and $\rho > 0$, represents rewards for attracting views, and wv, where $w \geq 0$ is a wage-per-view, represents payments from the platform.

Interpretation. Supply-side preferences are captured by μ_k, which allows the cost, expressive satisfaction, or status utility associated with producing a piece of content to vary with its type. Variation in μ_k drives a wedge between viewer and creator preferences if certain types have high μ_k but low m_k, or vice versa.

βv^{ρ} represents both nonpecuniary satisfaction from receiving attention and the ability to monetize attention through third-party sponsorships. Higher values of β and ρ help align viewer and creator preferences by encouraging creators to produce content types that viewers like and will therefore receive higher viewership.[7]

Per-view wages w similarly align viewer and creator preferences. Imposing a common (not type-specific) wage is simpler and is inconsequential for our theoretical results, as explored in Appendix F.1.

Creator heterogeneity. Creators vary in their skill at producing different types of content. We capture this by assuming that within type k, each creator belongs to one of a finite number of internally homogeneous groups indexed by g. The quality q_p and shocks $\{e_{ip}\}_{i \in I}$ of a piece of type k created by a member of group g are drawn from a type- and group-specific joint distribution F_{kg}. A creator's group can differ across types; when we discuss creator j producing type k, g denotes j's group for type k.

Timing. The timing of the game proceeds as follows.

1. The platform sets a wage per view w.
2. Each creator draws a separate cost shock κ_{jk} for creating each content type, and a shock for not creating, from a common type-I extreme value distribution with scale $1/\psi$. They create up to one unit of one type.
3. The platform observes the q_p, e_{ip} shocks of produced posts and assigns each viewer a set of posts P_i.[8]
4. Viewer i enters the platform with a reservation value of time $\underline{u}_i(T)$ increasing in the mass of posts T they have consumed. She consumes the subset of P_i that maximizes her utility accounting for her opportunity cost of time and diminishing marginal utility within content types.

Platform's objective. We assume the platform extracts viewer surplus through price discrimination.[9] It therefore sets the wage w and assigns posts to viewers to maximize viewer surplus net of wage costs.

[7] We could allow β and ρ to vary by content type, thereby introducing another possible wedge between viewer and creator preferences. We impose homogeneous β and ρ for two reasons. First, it is simpler and, as we show in Appendix Figure A8, empirically inconsequential. Second, if content type k had higher β_k because it created more sponsorship opportunities, it would not be obvious whether to interpret β_k as a supply-side preference. On the one hand, it would ultimately derive from appropriation of *viewer* surplus arising from demand for the sponsored product. On the other hand, creators could be biased towards content types where sponsorship availability makes viewer surplus more appropriable, particularly if wages hit a zero lower bound.

[8] We assume measurement of q_p and e_{ip} is accomplished through a preliminary experimentation step where the platform serves a new piece p to a small subset of viewers and infers its quality q_p through their average engagement and the distribution of its e_{ip} by combining their engagement with an estimate of the covariance matrix of viewer preferences based on past behavior ("viewers like you liked..."). We do not model this experimentation step, but we trace it out empirically later.

[9] This need not occur via a literal price and could, for example, occur via personalized ad loads (Beknazar-Yuzbashev et al., 2025b).

Specifically, it assigns viewer i the set P_i^* solving $\max_{P_i} \int_{P_i} \left(u_{ip} - \gamma h_{ik(p)}\right) dp - \int_0^{|P_i|} \underline{u}_i(t)\, dt$. We will see below that P_i^* is unique and simple to characterize.[10]

Intuitively, the platform serves the viewer her favorite posts of each type until their appeal drops so low, or her opportunity cost of time rises so high, that she switches off. Because the viewer has an increasing opportunity cost, pieces of different types compete for her attention: if the platform gets access to a better pool of comedy sketches, the additional sketches inserted into her feed may crowd out incumbent pieces.

Further discussion of setup. Appendix F.1 provides further discussion of aspects of our setup, including robustness of our results to competition between platforms and type-specific wages and empirical tests of whether platforms algorithmically "subsidize" certain content types over others.

Equilibrium concept. An equilibrium consists of a wage w^*, and, for each $w \geq 0$, creator strategies mapping cost shock realizations $\{\kappa_{jk}\}_k$ into actions, such that creators best-respond to each other given each wage, and w^* maximizes expected viewer surplus minus wage payments given creator strategies.

Assumptions. We assume that for each i, $\underline{u}_i(.)$ is continuous and weakly increasing and $\underline{u}_i(0)$ is low enough that i consumes a strictly positive mass of posts; and that the distribution of $q + e_i$ under each F_{kg} is atomless.

Lemma 1 characterizes the equilibria of this game. Proofs are in Appendix F.

Lemma 1. An equilibrium exists. In any equilibrium, working backwards:

1. Viewer i sees the unique (up to measure zero) subset P_i^* of produced pieces maximizing her utility.

   Specifically, let T_i be the mass of posts consumed by viewer i and let h_{ik} be the share of viewer i's consumption going to type k. Define viewer i's "attention price" τ_i as $\tau_i := \underline{u}_i(T_i) - \gamma \sum_\ell h_{i\ell}^2$ and her type-specific cutoff t_{ik} as $t_{ik} := \tau_i + 2\gamma h_{ik}$. Then:

   $$P_i^* = \{p : u_{ip} \geq t_{ik(p)}\}$$

2. Production results from creators' utility maximization given expectations about viewership.

   Specifically, given others' behavior, creator j produces type k with probability σ_{jk} satisfying

   $$\log \frac{\sigma_{jk}}{\sigma_{j0}} = \psi\Big(\underbrace{\mu_k + \widetilde{\mu}_{jk}}_{\text{effort cost and expressive satisfaction}} + \underbrace{\mathbb{E}_{F_{kg}}\left[\beta\big(\textstyle\sum_i \mathbb{1}\{u_{ip} \geq t_{ik}\}\big)^\rho + w \sum_i \mathbb{1}\{u_{ip} \geq t_{ik}\}\right]}_{\text{rewards from viewership}} \Big)$$

   where σ_{j0} is the probability that j does not produce and $1/\psi$ is the scale of the cost shocks.

3. The platform's wage w^* trades off the increase in expected viewer surplus from the additional production induced by higher wages against the increase in the wage bill.

   Specifically, let $V := \sum_i T_i$ be total views. If $w^* > 0$, it satisfies the first-order condition

   $$\underbrace{\int_J \sum_k \frac{d\sigma_{jk}}{dw}\, \mathbb{E}_{F_{kg}}\Big[\textstyle\sum_i (u_{ip} - t_{ik})^+\Big]\, dj}_{\text{increase in viewer surplus from higher production}} = \underbrace{V + w^* \frac{dV}{dw}}_{\text{increase in wage bill}}$$

[10] For simplicity we assume the platform ignores the wage when assigning posts, meaning utility from the marginal assigned post is $\geq \underline{u}_i(T)$ rather than $\geq \underline{u}_i(T) + w$. This is inconsequential for our results and adds descriptive realism: (i) platforms do not algorithmically penalize posts eligible for per-view payments and (ii) platforms serve viewers an infinite feed of posts rather than cutting them off from scrolling at some point. We also assume the platform does not assign the viewer posts she will not consume.

We now move on to our first substantive result: equilibrium consumption of each content type can be described in terms of separate components depending only on demand- versus supply-side preferences.

Proposition 1. At any equilibrium wage w, equilibrium consumption shares are a fixed point that can be characterized as follows. Begin by stipulating a vector of cutoffs $\boldsymbol{\tau} = \{\tau_i\}_i$ for appearing in each viewer's feed and a vector $\boldsymbol{h} = \{h_{ik}\}_{i,k}$ of shares of each content type in each viewer's feed.

1. **(Demand)** A creator from group g producing type k faces a cumulative distribution D_{kg} of potential views that depends only on demand-side parameters and equilibrium cutoffs and shares:
$$D_{kg}(v, \boldsymbol{\tau}, \boldsymbol{h}) = \mathbb{P}_{(\{e_i\}_{i\in I}, q)\sim F_{kg}}\left[\sum_{i\in I} \mathbb{1}\{m_k + \widetilde{m}_{ik} + q + e_i - 2\gamma h_{ik} \geq \tau_i\} \leq v\right] \tag{3}$$
2. **(Supply)** The supply of pieces of type k from group g can be written as a function $S_{kg}(\boldsymbol{D})$ of the viewership distribution $\boldsymbol{D} = \{D_{kg}\}_{k,g}$, where $S_{kg}(.)$ depends only on supply-side parameters:
$$S_{kg}(\boldsymbol{D}) = \int_{\{j: g_k(j)=g\}} \frac{\exp\left(\psi(\mu_k + \widetilde{\mu}_{jk} + \mathbb{E}_{D_{kg_k(j)}}[\beta V^\rho + wV])\right)}{1 + \sum_\ell \exp\left(\psi(\mu_\ell + \widetilde{\mu}_{j\ell} + \mathbb{E}_{D_{\ell g_\ell(j)}}[\beta V^\rho + wV])\right)} dj \tag{4}$$
3. **(Consumption shares)** Consumption of type k can be written as a function of supply and demand:
$$C_k = \sum_g S_{kg}(\boldsymbol{D}) \mathbb{E}_{D_{kg}}(v) \tag{5}$$
Aggregate consumption results from a vector of individual consumption $\{C_{ik} = \sum_g S_{kg}(\boldsymbol{D})\, \mathbb{P}_{F_{kg}}[m_k + \widetilde{m}_{ik} + q + e_i - 2\gamma h_{ik} \geq \tau_i]\}_{i,k}$ generating the stipulated vectors of cutoffs and feed shares: $\tau_i = \underline{u}_i(\sum_\ell C_{i\ell}) - \gamma \sum_\ell h_{i\ell}^2$ and $h_{ik} = C_{ik}/\sum_\ell C_{i\ell}$ for all i, k.

Proposition 1 says that three sets of parameters determine equilibrium consumption of content type k. The interaction of these parameters is visualized in Figure 1 Panel (a), which plots the quantity of type-k posts produced on the x-axis and the average viewership of type-k posts on the y-axis. Aggregate consumption is the area of the shaded rectangle: the product of quantity of posts and average viewership per post.

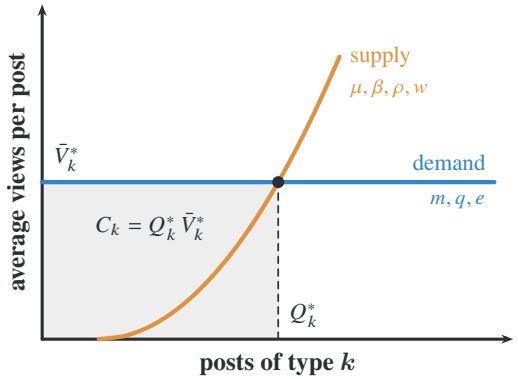

First are the demand-side parameters capturing viewers' taste for type k: the more viewers like type k's distinctive characteristics, the more views a piece of type k will receive. In Figure 1 Panel (a), these parameters determine the height of the blue demand curve—the average viewership a post of type k receives.

Second are the supply-side parameters μ_k affecting creators' taste for producing type k. The more creators enjoy producing type k, the more pieces they will create. Even if m_k is low, meaning viewers dislike type k's distinctive characteristics, pieces of type k can make it into viewers' feeds through lucky draws of q and e. More production entails more shots at that. In Figure 1, higher values of μ_k shift the orange supply curve outwards by making creators more willing to supply content at any given level of expected viewership.

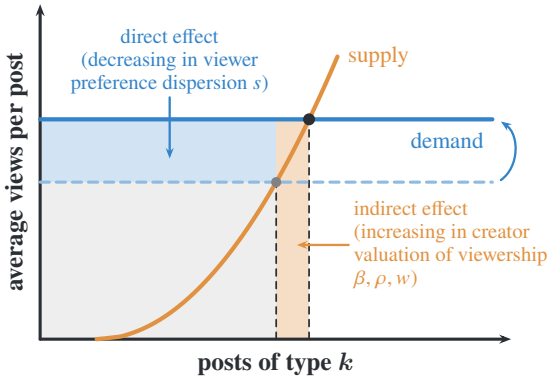

Third are the supply parameters β, ρ, w governing creators' utility from attracting viewership. These parameters mediate the feedback from demand to supply: the more that viewers like watching type k, the more viewership a creator will expect for producing type k, and therefore the larger the number of creators who will choose to produce type k in pursuit of wages and attention. In Figure 1, higher values of these parameters flatten the supply curve, amplifying the effects of a given vertical demand shift on consumption.

Figure 1: *Supply, demand, and equilibrium content consumption*

(a) *Equilibrium consumption C_k of content type k*

(b) *Comparative statics: parameters mediating the effect of an increase in average appeal m_k*

Notes: This figure plots the "demand" and "supply" curves determining equilibrium consumption of content type k under the simplifying assumptions that there is no diminishing marginal utility ($\gamma = 0$), type k is a small enough share of feeds that it does not affect viewers' τ_i, and creators make entry decisions according to the mean of expected viewership rather than its full distribution.

Comparative statics. Two factors mediate the influence of supply- relative to demand-side preferences on equilibrium consumption: the within-type residual dispersion of viewer preferences (governed by the variance of the $q + e_i$ shocks), and the sensitivity of creators' utility to viewership (governed by β, ρ, and w).

Proposition 2. Suppose there are two content types, H and L, which are produced by a homogeneous group of creators at a fixed wage $w > 0$ and are identical except that viewers prefer H ($m_H > m_L > 0$) and creators prefer L ($0 < \mu_H < \mu_L$). Each viewer i consumes a mass $T_i > 0$ of posts, each creator chooses one of the two types to produce, and there is no diminishing marginal utility within type ($\gamma = 0$).[11]

Without loss of generality, write the distribution of $q + e_i$ as $s\xi$, where $s > 0$ is a scalar governing the degree of residual preference dispersion. Then in both the highest and lowest equilibria in terms of H's share of production, we have that:

1. **(Preference dispersion attenuates the effect of demand.)** The production and consumption shares of H content are decreasing in viewer preference dispersion s.
2. **(Preference dispersion deprofessionalizes production.)** Let $R(s)$ denote the equilibrium ratio of creator utility from wages to intrinsic utility from μ. Then $R(s)$ is decreasing in s.
3. **(Preference dispersion makes content locally scarce.)** Let p be any of the T_i produced pieces with the highest $q+e_i$ draws for viewer i. The probability that $|(q_p+e_{ip})-(q_{p'}+e_{ip'})| < m_H-m_L$ for a random produced piece p' is decreasing in s.
4. **(Creator valuation of viewership amplifies the effect of demand.)** The production and consumption shares of H are increasing in β, ρ, and w.

Preference dispersion. Proposition 2 says that increasing the average appeal of content type k has an effect on its consumption that is *attenuated* by the degree of residual viewer preference dispersion, captured by

[11] The proposition requires us to hold aggregate consumption and production fixed. Loosely speaking, this is because it captures mechanisms that hold when we compare states of the world with similar total surplus but different distributions of this surplus across primitives. Increasing s, β, or ρ changes the relative importance of different primitives but also increases total surplus. Capturing our mechanisms of interest requires shutting down the latter channel by holding aggregate consumption and production fixed.

the variance of the q and e_i shocks. Intuitively, greater dispersion of the q and e_i shocks creates residual variation in utility that tends to wash out the importance of fixed differences in baseline appeal.

Figure 2 illustrates the key intuition by plotting the distributions of utility viewer i derives from pieces of content types L and H, whose mean appeals m_L, m_H differ by Δ. When the variances of the shocks are low, as in Panel (a), an L piece is very unlikely to receive a $q + e_i$ draw so favorable that it can beat out the best available H content. Higher variances make this more likely and, by increasing the dispersion of utility, reduce the probability that the fixed baseline utility gap Δ is decisive in a viewer's ranking of a pair of L and H pieces competing for membership in her feed.

Scarcity. We can also think about preference dispersion through the lens of *scarcity*. We have hypothesized that a viewer who *ceteris paribus* prefers moderation may nevertheless be served pieces of extreme political content because they are more amusing than the best available moderate content. This assumes local scarcity of highly amusing content. Preference dispersion endogenously creates such scarcity by causing pieces to be distributed more sparsely in utility space and making each one less likely to have close substitutes.

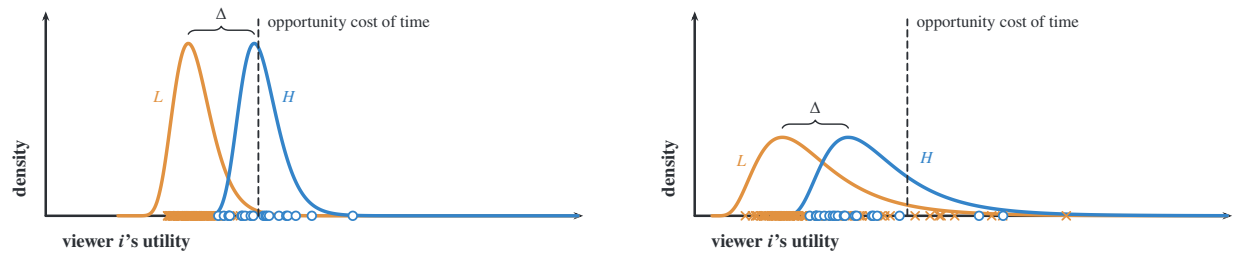

This is even more intuitive if we think of high-variance q and e_i shocks as representing high-dimensional viewer preferences, where each additional dimension on which a piece matches a viewer's preference adds to the piece's utility. High-dimensional preferences slice the content space into a very fine grid and thereby create local scarcity of content around a viewer's ideal point.[12]

Deprofessionalization. Greater viewer preference dispersion also "deprofessionalizes" production. When viewership becomes highly unpredictable, it becomes difficult for a creator to consistently earn high wages by producing a content type with large m_k and attracting high and stable viewership. Viewership becomes dispersed over many creators and production instead becomes driven by intrinsic satisfaction μ_k.

Creator valuation of viewership. Proposition 2 also notes that the parameters β, ρ, and w amplify the effects of demand-side tastes m_k by mediating the feedback from demand to supply. If creators face a high wage-per-view or derive substantial nonpecuniary satisfaction from attracting more views, they will be pulled towards producing the content types demanded by viewers, amplifying the importance of m_k. By contrast,

Figure 2: *Preference dispersion and pass-through of production to consumption*

(a) *Low dispersion, low pass-through* ***(b)*** *High dispersion, high pass-through*

Notes: This figure shows the effects of increasing viewer preference dispersion—the variance of the q and e shocks—holding fixed $m_H - m_L$ and the expected amount of content falling above the focal viewer's opportunity cost of time.

[12] The curse of dimensionality offers one way to make this quantitatively intuitive. If content is uniformly distributed over fifty binary dimensions viewers care about, the probability that a random piece is in a viewer's top preference bucket is about one in a thousand trillion. If a platform has a billion pieces, a viewer's favorite hundred will on average differ from her ideal on seven out of fifty dimensions, and from each other on twelve.

if wages are low and creators derive little satisfaction from viewership *on the margin*—either because β is low or because ρ is low, reflecting strongly concave satisfaction from viewership—this feedback weakens.

Equilibrium wages on Instagram, TikTok, and X/Twitter are in fact very low. This can occur for multiple reasons. It can occur if nonpecuniary motivations suffice to induce substantial production, meaning higher wages would largely transfer money from the platform to inframarginal creators. It can also occur due to a market failure *exacerbated* by inter-platform competition (Jeon and Rey, 2024). Suppose platforms cannot enforce exclusivity contracts on creators. (They in fact do not, likely due to practical difficulties enforcing such contracts.) Then a platform could raise its wages to induce new content creation, but could not appropriate the resulting viewer surplus because this content would also be cross-posted on rival platforms—a practice our survey of creators shows is commonplace. This could explain why YouTube, which has no close competitor for longer-form video content, pays much higher wages, a point to which we return below. We remain agnostic between these explanations for low prevailing wages.

Summary. The model just outlined shapes our subsequent empirical investigation in two ways.

First, it helps define our empirical objectives. We have shown how to write equilibrium content consumption in terms of separate objects depending only on demand- and on supply-side preferences. In Section 4 we estimate these objects and analyze counterfactuals in which we equalize content types' supply- or demand-side preferences to decompose observed consumption into supply- vs. demand-driven components.

Second, it generates two predictions about the conditions under which supply-side preferences will influence equilibrium consumption. In Sections 3.2 and 4.2, we show that viewer preferences exhibit high dispersion that creates local scarcity of content matching viewer preferences and attenuates the effects of average taste differences on consumption. In Section 4.3, we show that creators' marginal valuation of viewership is low due to low wages and strongly concave nonpecuniary rewards to attention.

2.2 Social versus legacy media

We now explain how the social media business model just described differs from that of legacy media and why it magnifies the influence of supply-side preferences and encourages short-form content.

Goldman's Law. Our model assumed that pieces of content emerge stochastically from a high-dimensional characteristic space. This assumption is motivated by two stylized facts in media economics (Caves, 2003). The first is that it is extremely difficult to predict ex-ante which pieces of media will resonate with audiences (Waldfogel, 2019). This is sometimes called "Goldman's Law," after the screenwriter William Goldman's insistence that "the single most important fact, perhaps, of the entire movie industry [is that] *nobody knows anything*" about which projects will appeal to consumers (Goldman, 1983). Quantitative studies of legacy entertainment industries bear out this assertion (De Vany and Walls, 1999). Goldman's Law also seems to be in force on social media, where creators routinely express profound puzzlement about what draws audiences to their content and why seemingly identical videos end up differing wildly in performance (Andrews, 2020; Sweet, 2023; Tait, 2023; Cruz, 2024; Ronson, 2026; O'Meara, 2026).[13]

Second, media consumers' preferences exhibit extreme heterogeneity: for example, different evaluators' assessments of media correlate only very weakly for movies (Wallisch and Whritner, 2017), images (Vessel

[13] Appendix F.1 discusses the alternative interpretation that Goldman's Law reflects strategic complementarities in consumption.

and Rubin, 2010), jokes (Rosenbusch et al., 2022), and poems (Belfi et al., 2018).

Institutional background on legacy media. Pre-Internet media outlets faced the same unpredictable and heterogeneous consumer preferences as social media platforms. But they were constrained by two factors (Waldfogel, 2019). First were technological bottlenecks on distribution. The broadcast spectrum only supported three TV channels; cable supported a few dozen to a few hundred; cinemas had only a few screens; bookstores could only stock so many books (Brynjolfsson et al., 2003). Outlets could therefore distribute only a limited amount of content, preventing them from fully catering to preference heterogeneity.

Second were high costs of audience testing. The expense and inconvenience of distributing content prevented outlets from efficiently testing new pieces of content on large samples of consumers to learn their quality before making a decision about wider distribution (Goldman, 1983). For example, test screenings for movies were expensive and tended to yield noisy and unrepresentative samples (Lumet, 1995).

Faced with these difficulties, outlets professionally produced small portfolios of content ex-ante optimized, to the extent possible, to appeal to viewers. They then distributed them widely without extensive testing, gambling on opening weekend or the first post-release weeks of a book or album (Waldfogel, 2019).

Effects of the Internet. The Internet eliminated physical constraints on both personalized distribution and cheap at-scale collection of feedback. Unlike a TV network, a website with a large content library could serve a distinct feed to each visitor at zero marginal cost, and quickly collect feedback in the form of views and shares. This enabled sites with large libraries to rapidly test new pieces of content on large subsets of consumers and use the resulting feedback to inform selective further distribution to other consumers.[14]

Platforms such as Netflix and Amazon deployed these capabilities to streamline distribution of movies, TV shows, and books, increasing the productivity of legacy media and leading it to expand in quantity and quality (Waldfogel, 2019; Aridor et al., 2026). But as with many new technologies (David, 1990), fully harnessing the Internet's potential for media required a more fundamental redesign of the underlying product. By giving platforms the tools to sift through large libraries of content and locate the best pieces to distribute to each viewer, the Internet raised the returns to content library *scale* and thereby rewarded content that is *cheap to procure at scale*—for example, low-effort content that is satisfying to produce—and *disaggregated enough to facilitate granular cherry-picking and personalization*—for example, short-form content.

Increase in supply-side influence. A toy version of our model illustrates. Suppose there are two types of content, L and H, with mean appeal to viewers $m_L < m_H$ and per-unit procurement costs $c_L < c_H$. That is, L content is less appealing but is also cheaper to procure. When produced, a piece j of L or H content draws vertical q_j and horizontal $\{e_{ij}\}_i$ appeal shocks from a distribution common to both types. An outlet procures some pieces, distributes one to each viewer, and maximizes viewer surplus net of procurement costs.

Consider an outlet unable to act on the q, e shocks when distributing content. This outlet optimally procures a single unit of H and distributes it to everyone. This represents legacy media: absent the ability to ex-post cherry-pick or personalize, an outlet should produce a little of the ex-ante most appealing content.

[14]This strategy was pioneered by Facebook and Twitter, neither of which initially used recommendation algorithms. Instead, they relied on users to surface and spread high-quality content by deciding what to share or repost, and to personalize their own feeds by deciding who to follow or connect with. They thereby reproduced the decentralized "testing" and dissemination of products through repeated marketplace interactions and social learning, but at vastly greater speed than physical markets. Fueled in part by data from these networks, advances in machine learning then led to algorithms that greased the wheels of this process.

When we introduce the Internet—allowing the outlet to experimentally uncover the q and e shocks and act on them via personalized distribution—the outlet is incentivized to procure several pieces of H content rather than just one. This strategy represents Netflix and Amazon: expand production of legacy media types.

But the outlet may be able to do even *better* by spending the same budget procuring a larger number of L pieces, compensating for their lower average appeal with a larger number of draws enabling superior cream-skimming of the best q and e draws. This represents social media.

The shift from content types with high average appeal m to those with low procurement costs c—which ultimately derive from the supply-side preferences determining creators' reservation wages—is the sense in which social media's business model magnifies the influence of supply- relative to demand-side preferences.

Welfare. This shift leads viewers to consume content with lower m but higher q, e. In principle, this increases viewer surplus on net. But if particular internalities or externalities load on the dimensions distinguishing L from H, welfare could decrease. For example, if $m_L < m_H$ because L content is more likely to trigger unfavorable social comparisons, and viewers underestimate the long-run psychological effects of repeated exposure to such comparisons, they could end up less happy. Or if L content represents partisan vitriol and H represents factual reporting, this shift could reduce welfare via negative externalities for politics.

Short-form content. Finally, suppose the q and e draws are separately realized across different subunits of longer pieces of content: for example, some of the jokes in a comedian's stand-up routine are better than others, or some scenes in a movie appeal more to i and others to i'. Then an outlet able to observe, and condition distribution on, q and e benefits from splitting content into the smallest subunits over which these shocks are realized, to enable maximally granular ex-post discrimination. Appendix F.3 provides evidence that such discrimination is extensive on social media and summarizes two other mechanisms: (i) short-form content allows more rapid learning about viewer preferences by linking higher-frequency user interaction data to more disaggregated variation in exposure to content characteristics;[15] and (ii) reducing the minimum required length of content lowers barriers to content production.[16]

3 Observational Evidence

This section provides observational evidence documenting the importance of nonpecuniary supply-side preferences on social media. It proceeds in two steps.

In the first step, we focus on two ways in which it might *fail* to be the case that nonpecuniary supply-side preferences influence consumption: if production is dominated by professional creators who cater to viewer

[15] The nascent "microdrama" industry operates according to this logic: produce large volumes of short, cheap entertainment, rely on algorithms to engage in granular experimentation and ex-post matching to viewers, and use variation in performance to learn which specific story beats and set pieces do well with viewers (Kolitz, 2026); see also Bao (2026).

[16] Conventional explanations often claim social media content is short-form because the format hijacks our brain's susceptibility to being tempted by uncertain, variable, and immediate rewards, like those offered by slot machines. But this fails to explain what makes social media different from TV, where content could also be structured to exploit these vulnerabilities, and plausibly *is*. Indeed, 20th-century critics accused TV channels of fragmenting viewers' attention spans by serving them loosely connected sequences of short clips: Postman (1985) writes that "what [TV viewers] watch, and like to watch, are moving pictures: millions of them, of short duration and dynamic variety," and Pynchon (1990) describes a satirical TV-detoxification facility as serving "a retinal diet of scientifically calculated short video clips of what in full dosage would, according to theory, have destroyed [the subject's] sanity." One way to rescue conventional theories is to append an additional claim about how the tactile sensation of swiping or scrolling somehow activates or exacerbates these psychological vulnerabilities.

preferences in pursuit of pecuniary rewards, or if content is so abundant that supply-side constraints never bind. Our model predicted that sufficiently unpredictable and dispersed viewer preferences will cause both of these conditions to fail. We document a series of facts confirming this prediction, showing that viewer preference dispersion deprofessionalizes content production and creates local content scarcity.

In our second set of results, we provide evidence that supply-side preferences specifically drive production of status-oriented "lifestyle" and partisan political content.

3.1 Data

We provide an overview of the data underlying results in this section, with further details in Appendix C. Figure 3 summarizes our data collections, including the experiments introduced in Section 4.

Recruitment. We recruit social media *viewers* from the survey platforms Prolific and MobLab, as often done in the literature (e.g., Allcott et al., 2025). We recruit *creators* via Prolific and through an email campaign targeting creators who appear in the viewership histories of our respondents (see below).

Our recruitment procedures involve one innovation relative to preceding literature: across most data collections, we require respondents to begin by logging in with their social media accounts using an authentication flow we developed drawing on the TikTok Login Kit, the X/Twitter `users.read` API, and Google OAuth. The tool collects and authenticates respondents' social media profiles and checks their numbers of posts and followers before letting them into our surveys. This allows us to verify that they genuinely use these platforms, to screen out respondents whose accounts fall below certain size thresholds for our creator experiments, and to scrape respondents' accounts to recover the contents of their recent posts.

Appendix Tables A1–A4 compare our samples to nationally representative surveys from Pew, YouGov, and the American National Election Studies that ask about usage of specific social media platforms. Relative to the general youth population, users of our platforms, especially TikTok, skew more female, left-wing, and ideologically extreme. Our samples skew even further in these directions as well as being more educated.

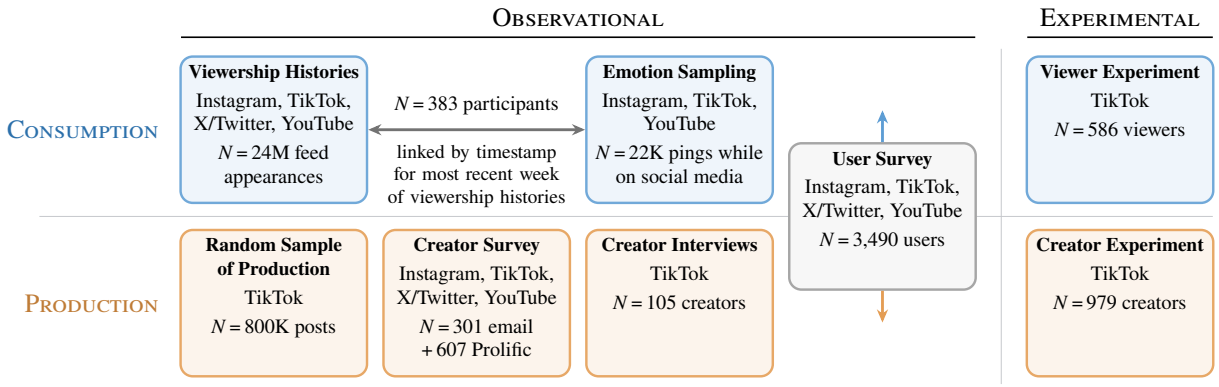

Viewership histories and emotion-sampling. Our data on the contents of users' social media feeds and their contemporaneous emotions come from a panel of 383 Americans aged 18-30 recruited from Prolific.[17]

We pay participants to download our iPhone app, which pings them randomly throughout the day—with particularly high frequency when it detects they are using social media—and asks about their emotions. After a week of using it, participants download and send us their viewership histories on Instagram, TikTok, and YouTube. Their final payment depends on submission of these histories and their response rate to the app's notifications. Appendix Table A5 traces out attrition from our screening survey through to completion. Persistence selects on gender (being female) and politics (being liberal) but not education, income, or mental health. Because we have no randomized treatment, standard concerns about selective attrition do not apply.

Instagram, TikTok, and YouTube comply with data ownership regulations in the EU and California by giving users the option to download their data, which is where our viewership histories come from. These histories contain second-by-second records of each post the user has viewed and each search they have made, reaching back one week, six months, and all time, respectively, for the three platforms, totaling 24 million

[17] Our hypotheses and empirical strategy for estimating the effects of social media content on emotions were pre-registered on the Open Science Framework at `https://osf.io/8ctq7`.

Figure 3: *Overview of data collections*

posts across all respondents and platforms. We link these histories by timestamp to the emotion responses collected via our app, allowing us to observe exactly which post a respondent was viewing when they were pinged by our app. Appendix Table A6 describes the characteristics of these histories.

X/Twitter's "request my data" feature does not yield comparable data, so we follow up with participants and pay them to briefly use a Chrome extension that records the top 300 posts on their X/Twitter feed; we obtain these data, which are not linked to emotions, for 57 respondents.

Random sampling of produced posts. In addition to viewership histories for a panel of users, TikTok offers a Research API that allows us to randomly sample from the pool of posts produced on the platform in the US in any specified date range. This allows us to compare a representative sample of the content *produced* on TikTok to the TikToks appearing in viewers' feeds. For this reason, as well as other data-quality reasons described in Appendix C, we focus most of our results on TikTok, showing results for other platforms in Appendix B (to the extent our data allow).

Post metadata and classification. We take the post URLs appearing in our viewership histories and API-based random sampling and scrape characteristics of those posts, including thumbnail images, captions, transcripts, and metadata (including view counts and flags for commercial sponsorships or ad spending). We give each post's imagery and text metadata to `GPT-5-mini` and ask it to assign the post a content category based on a classification schema described in Appendix C. The schema was developed on the basis of open-ended data gathered from social media users. The LLM classifications are validated against 100 human hand-coders recruited on Prolific, as shown in Appendix Table A9; human codings correlate strongly with the LLM codings, and humans agree slightly more with the LLM than with each other. Appendix C applies a sparse auto-encoder (Movva et al., 2025; Carlson, 2026) to our experimental and observational data stripped of classifications and shows that it autonomously discovers categories similar to our classifications.

Creator survey. We conduct a descriptive survey of creators who produce content on the platforms we study. We contact creators in two ways. First, we scrape the profiles of creators who appear in our respondents' viewership histories and extract email addresses where available. We email creators and offer Amazon gift cards in exchange for completing our survey, collecting 301 responses at a 1.7% response rate. Second, we recruit 607 creators on Prolific, using our social media log-in flow to automatically screen out small accounts.

Our viewership history data, which allow us to see the characteristics of creators appearing in viewers' feeds, allow us to re-weight our survey responses to create a sample representative (in terms of observables such as follower counts and types of content posted) of the creators appearing in viewers' feeds. In our emails, we randomly offer either $5 or $10 gift cards to test whether responses are selected on unobservables (Dutz et al., 2026). Appendix Table A12 shows the $10 offers significantly increase response rates and the resulting test shows no evidence of selection on unobservables.

User survey. To measure selection into content creation, we survey 3,490 users of our platforms recruited through Prolific. We ask respondents to log in with their accounts, allowing us to automatically grab their numbers of followers and posts and to scrape the contents of recent posts from their profiles.[18] We then elicit survey outcomes and correlate those outcomes with features of their posting behavior, as described later.

Qualitative interviews. We follow up with a sample of 105 creators who participated in our surveys or experiments and ask them to complete a 15-minute AI-conducted qualitative interview (Chopra and Haaland, 2023; Geiecke and Jaravel, 2024). The interviewer asks a series of open-ended questions about what types of content the interviewee posts and why they post. It then asks probing followups seeking concrete details about the satisfaction interviewees derive from creating posts or attracting likes or views and about why they might be reluctant to post certain types of content. Quotes from these interviews are collected in Appendix K and we refer to them throughout the paper to enrich our quantitative results.

3.2 Viewer preference dispersion deprofessionalizes production and creates scarcity

Motivation. Our first set of results focuses on ruling out two possibilities under which nonpecuniary supply-side preferences will *fail* to influence consumption. One possibility is that consumption consolidates around professional creators who produce content that caters to viewer preferences in order to maximize the size of their audiences and thereby earn income from platform wages or third-party sponsorships. Another possibility is that platforms' content libraries are so vast that they can always find content perfectly matching viewer preferences and never have to make a concession to supply-side scarcity constraints.

Our model predicted that sufficiently unpredictable and dispersed viewer preferences will forestall both of these possibilities. In this section, we start by documenting extreme viewer preference dispersion. We then show how this (i) deprofessionalizes production and (ii) creates local scarcity of appealing content.

Because our richest linked data on production and consumption come from our TikTok viewership histories plus TikTok's Research API, results in this section focus on TikTok. At the end of the section, we briefly discuss the analogous results for other platforms, which are presented in Appendix B.

3.2.1 Preference dispersion

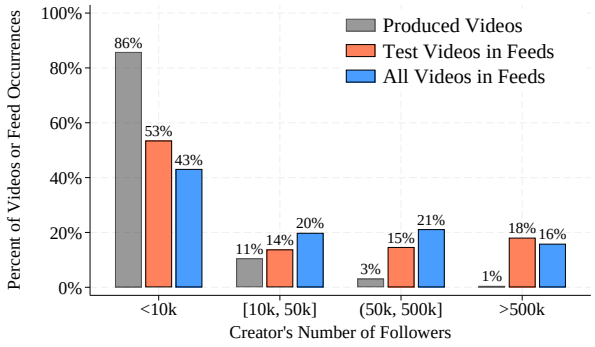

We demonstrate preference dispersion by tracing TikTok content from initial production to final consumption.

Distribution of production. The grey bars in Figure 4 Panel (a) use a representative sample of all videos produced on TikTok between November 2025 and February 2026. Panel (a) plots the distribution of the follower counts of these videos' creators, a measure of those creators' size and prominence. The panel shows that nearly 90% of production on TikTok comes from very small creators with fewer than 10,000 followers.

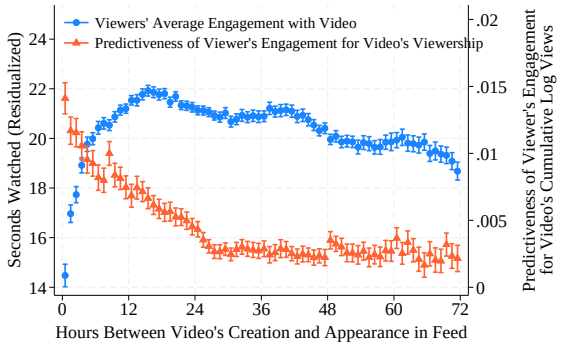

[18] Since Instagram does not expose any API or toolkit allowing us to build a login flow, we ask users directly for their handles.

Figure 4: *Production, experimentation, and consumption on TikTok*

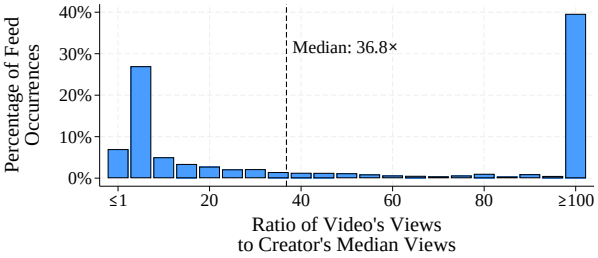

(a) *TikTok's experimentation and viewers' feeds draw heavily on the large base of production by small creators (<10k followers)*

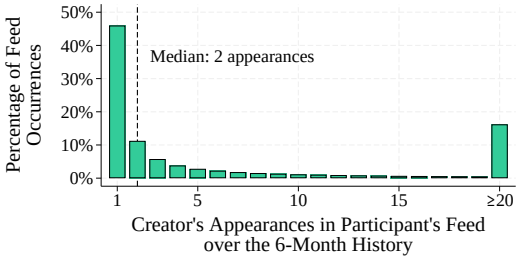

(b) *Experimentally tested videos can be identified as videos that appear in a viewer's feed shortly after being posted*

(c) *The videos viewers see are in the far upper tail of their creators' views*

(d) *Nearly half the videos viewers see are from creators they see once and never again*

Notes: Panel (a) plots the percentage of videos falling into each creator-size bucket in three different samples: (1) a random sample of the videos produced on TikTok, from its Research API; (3) all videos appearing in the histories of participants who sent us their personal TikTok data; and (2) the subset of history videos that appeared in a participant's feed less than 5 hours after being posted. Panel (b) uses videos in participants' feeds and plots the number of hours elapsing between the video being posted and appearing in the focal viewer's feed against (i) the average number of seconds watched by the participant (controlling for viewer by video duration fixed effects and time since the beginning of the session) and (ii) the slope between the focal viewer's engagement and the video's total log viewership scraped several months afterwards. Videos appearing less than 6 hours after being created make up 7% of the typical feed. Half of them are from creators the viewer has never seen before; in these cases they tend to come from small creators, with a median of 1,697 followers. Panels (c) and (d) use TikTok histories; an observation is a video occurring in a participant's feed. Panel (c) plots the ratio of a video's view count to the median view count of other videos posted by the same creator over the same period spanned by our histories. Panel (d) plots the number of times this observation's creator appears in the viewer's history.

If the ex-post variance of quality and taste shocks is *low* relative to predictable variation in creators' appeal, we should expect viewers to find and follow the creators whose content most appeals to them, and have feeds consistently filled with content from these creators. In this case, small creators would account for a large share of production but only a small share of consumption—their share of followership is 7.5%.

If, on the other hand, ex-post shock variance is *high*, we should expect appealing videos to emerge unpredictably from across the distribution of production, including from small creators who have not accumulated many followers. All social media platforms have mechanisms enabling discovery and dissemination of unexpectedly appealing pieces of content. For example, this might involve relying on users to directly spread such content by sharing or reposting it. In TikTok's case, this mechanism is deliberate experimentation.

Distribution of experimentation. When a video is posted, TikTok observes its creator, transcript, and imagery, and uses these to generate an imperfect prediction of its appeal (Boeker and Urman, 2022). TikTok then serves the video to a pool of "test" viewers and uses their engagement to resolve its residual uncertainty

about the video's quality and distribution of appeal before deciding whether and how to disseminate it.

Does TikTok deem videos from low-follower accounts worthy of testing? Panel (b) of Figure 4 shows that we can approximately identify test videos in our data by zooming in on videos that appear in a viewer's feed within a few hours of being posted. The blue coefficients show that such videos receive much lower engagement. A purely engagement-maximizing algorithm should equate viewers' engagement with marginal videos of all types, so this engagement drop suggests these videos are being inserted into viewers' feeds for an ulterior purpose. The orange coefficients show that viewers' engagement with these videos is highly predictive of their subsequent viewership, suggesting TikTok is learning from this engagement.

Panel (a) of Figure 4 shows that when selecting videos to test, although TikTok does statistically discriminate in favor of large creators, it draws from across the creator distribution. Creators in the smallest bin produce half of tested videos. This suggests that—conditional on a creator's baseline appeal as proxied by their follower count—TikTok expects there to be large ex-post video-to-video variation in appeal that is worth experimentally measuring so that it can be exploited for cream-skimming.

Distribution of consumption. TikTok's breadth of experimentation passes through to consumption. The blue bars in Panel (a) of Figure 4 plot the distribution of follower counts in viewers' full histories. Conditional on being tested, videos from large and small accounts are similarly likely to be broadly disseminated.

Consequently, *nearly half* of the typical feed is filled by creators from the bottom size bin. These are mostly one-off hits surfaced through experimentation that are outliers relative to their creator's typical output. Panel (c) shows that the median video in a viewer's feed receives 37 times more views than its creator's median views; for videos posted by creators in the bottom size bin, this ratio is 212. Panel (d) shows that 45% of the videos in viewers' feeds are from creators they see once and never again in the six-month window covered by their history. Appendix Figure A4 shows that only 11% are from creators who the viewer sees at least once per 10 hours of watching. (A proxy for following this creator, as we do not see following lists.)

Overall, the data decisively reject a world where most variation in appeal is ex-ante predictable and each viewer therefore consistently watches a fixed set of creators. Instead, unpredictable ex-post variation in appeal seems very large. TikTok responds by experimentally sifting through a broad swathe of produced content and filling viewers' feeds with the surprise one-off hits discovered this way.

3.2.2 Preference dispersion → Deprofessionalization

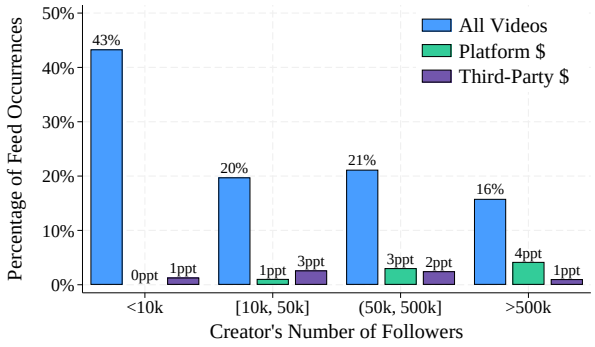

Our model predicted that high-variance ex-post shocks will prevent professional creators from consolidating viewership around themselves by catering to audiences' stable and predictable preferences. Indeed, it is not true that viewers mostly see content produced by professional "influencers."

Administrative earnings measures for videos in feeds. Panel (a) of Figure 5 uses scraped platform data to estimate the percentage of videos in viewers' feeds that make money. Green bars represent income from Creator Rewards, TikTok's program paying creators per view they receive. Eligibility for the program requires an account with at least 10,000 followers, a video that is at least a minute long, and satisfaction of a few other criteria. Only 9% of the videos in people's feeds are eligible to earn Creator Rewards.

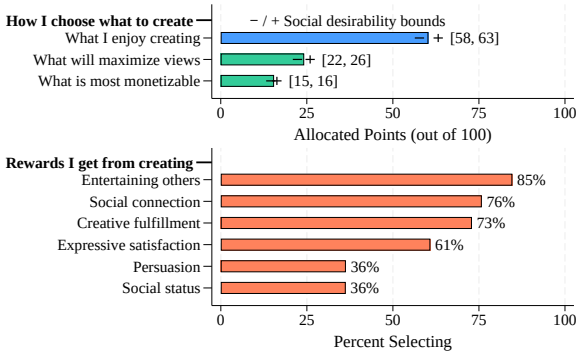

Purple bars represent income from third-party sponsors who pay a creator in exchange for featuring their

Figure 5: *Amateur-dominated production on TikTok*

(a) *Only a small fraction of the posts in viewers' feeds earn money for their creators (Admin data)*

(b) *Creators choose what content to make mostly based on nonpecuniary motivations (Creator survey)*

Notes: Panel (a) plots videos from the histories of participants who sent us their TikTok data. An observation is a video occurring in a participant's feed. Blue bars are the percent of observations in each creator size bucket. The green and purple bars plot how many observations in that bucket are (i) eligible for Creator Rewards (creator has at least 10k followers and 100k views in past 30 days and video is at least 60 seconds long and not sponsored) or (ii) tagged as sponsored. Bars are in percentage points, meaning, for example, that 1ppt out of 43ppt in the first bucket is sponsored. Panel (b) plots responses from our creator survey, with responses weighted by follower count and posting type to be representative of the creators viewers see in their feeds. The first sub-panel asks respondents to allocate 100 points between three possible considerations determining which types of content they choose to post. Answer options are 50/50 randomized between two sets intended to flip rankings of perceived social desirability as detailed in Appendix Figure A31. The second asks them to "tick all that apply" out of a list of nonpecuniary rewards they derive from producing content.

product. These sponsorships must legally be tagged in a way that shows up in the metadata we scrape. The figure shows that only 8% of the videos seen by viewers are tagged as sponsored. (Our sample includes ads, meaning videos someone has paid to boost into viewers' feeds; 7 out of 8 of these percentage points are ads.)

Earnings at the creator level. Appendix Figure A29 instead asks: how many of the videos people see come from creators who *ever* earn money, as suggested by the data we scrape and aggregate on all videos they post over a 3-month period? The figure also incorporates self-reported data from our survey of 908 creators, allowing us to get at income sources we cannot directly observe in the administrative platform data, such as unreported sponsorships, videos produced for sponsors' accounts, or donations from viewers.[19]

The figure shows that, depending on the conservativeness of our assumptions, up to around 45% of the videos viewers see on TikTok come from accounts that earn money on the platform. This is higher than the 15% of videos viewers see that directly earn money but still a minority. Moreover, our creator survey shows that even creators who make money create content for a mix of pecuniary and nonpecuniary reasons.

Survey of motivations. Our survey of 908 creators asks respondents about the considerations that influence what content they choose to create. We ask them to allocate 100 points between three options in proportion to their importance: do you create the content that will get the most views? The content that will attract the highest financial payouts? Or the content that you find personally satisfying to create? Panel (b) of Figure 5 plots responses, weighted to be representative of the creators in viewers' feeds.

Responses to such a question may be influenced by social desirability. We therefore randomize the wordings of the response options between two sets intended to flip their perceived social desirability, and

[19] Such income sources are commonly reported by creators in our survey, but are almost exclusively reported by creators who *also* earn money in administratively observable ways, suggesting that our extensive-margin estimates based on administrative tags of the share of creators earning money are close to the truth.

confirm in a supplementary survey detailed in Appendix Figure A31 that our manipulations succeed. The bars in the figure plot average responses, while the + and − symbols show average responses in each condition.

The figure shows that respondents report the most important consideration determining their production choices, by a wide margin, is what they personally find satisfying to produce.

We also ask creators to indicate which kinds of nonpecuniary satisfaction they derive from content production. Panel (b) shows that social connection, creative fulfillment, and expressive satisfaction are among the most popular answers, while a third of creators report gaining social status.[20] Appendix Tables A17 and A18 collect responses from our AI interviews to open-ended questions about why creators enjoy producing content or having people see it. We return to these answers in Section 4.3 when we discuss why the utility creators derive from posting appears to be so strongly concave in the number of views they receive.

Overall, nonpecuniary motivations appear to be by far the largest factor driving production.

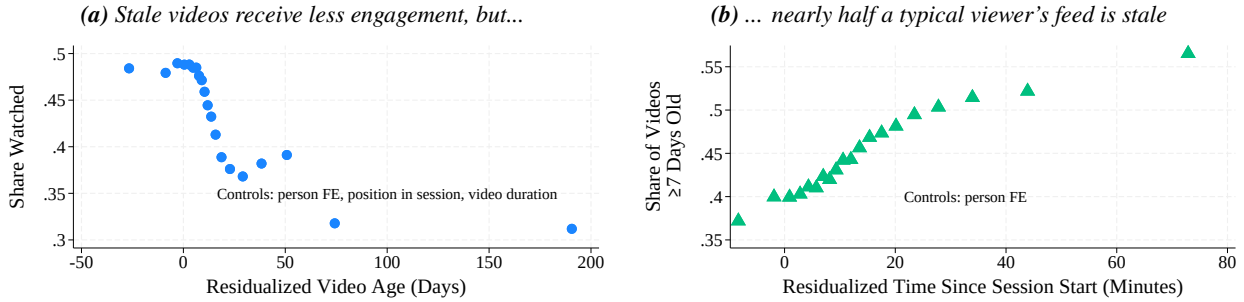

3.2.3 Preference dispersion → Scarcity

Our model also predicted that viewer preference dispersion creates local scarcity of content matching viewer preferences. This is because high-variance quality and taste shocks cause pieces of content to land in a more dispersed way in utility space, meaning each piece's closest substitute becomes further away.

Scarcity. Panel (a) of Figure 6 shows that viewers engage predictably and substantially less with "stale" videos—videos posted more than a week before they are served. If, each day, TikTok receives an abundant supply of fresh content closely matching a viewer's preferences, it should never serve her stale videos. But Panel (b) shows that from the moment the typical viewer begins scrolling, more than a third of the videos in her feed are stale; as she scrolls, this rises rapidly. This indicates substantial scarcity of highly appealing content, and the magnitude of this relationship—stale videos receive at least a 20% engagement penalty yet occupy up to half of the typical feed—suggests that the marginal appeal of available content falls very fast.

Scarcity and supply. Scarcity matters in our model because it prevents platforms from perfectly catering to viewers' preferences by serving them content with high baseline appeal *and* high q, e draws. Instead, it forces them to rely partly on pieces with lower baseline appeal but high q, e draws. Appendix Figure A5

Figure 6: *Local scarcity of appealing content on TikTok*

Notes: Panel (a) uses TikTok histories and plots the share of a video a viewer watches against the number of days since the video was posted (controlling for viewer by video duration fixed effects and time since the beginning of the session). Panel (b) plots the share of videos in a viewer's feed that were posted at least 7 days ago as a function of time since the viewer started this scrolling session, controlling for viewer fixed effects.

[20] Appendix Figure A11 shows that creators who report "expressive satisfaction" or "persuasion" are more likely to post political content on their accounts; those who report "social status" are more likely to post lifestyle content.

shows suggestive evidence that increases in scarcity increase TikTok's reliance on these kinds of pieces.

The figure draws on our classification of videos into seventeen genres described in Appendix C, such as "sports," "pets," or "food and cooking." We proxy for whether viewer i likes or dislikes a genre—her $\widetilde{m}_{ik}$—by whether it appears in her feed more or less commonly than among other viewers. Panels (a) and (b) show that videos from a genre viewer i dislikes that nevertheless appear in her feed score higher on the high-shock-draw measures from Figure 4—consistent with higher q or e realizations being needed to carry those videos into her feed. Panels (c) and (d) of Appendix Figure A5 show that as scarcity bites more keenly—as a viewer scrolls further into her feed, or as we compare lighter to heavier TikTok users—TikTok relies more on these unusually appealing outliers from disliked content types.

We view this test as suggestive because we lack exogenous variation in scarcity and because our model only predicts this slope under specific distributional assumptions (that $q + e$ have a locally increasing hazard).

3.2.4 Summary of dispersion evidence and discussion of other platforms

Summary. The descriptive patterns documented in this section validate the predictions of our model: the unpredictability and inscrutability of viewer preferences prevent professional creators from consistently optimizing for those preferences and instead lead platforms to engage in ex-post filtering from a broad base of amateur production. Moreover, preference dispersion creates local content scarcity that allows exceptional outliers from unappealing content types to enter viewers' feeds.

Other platforms. Appendix B reproduces these analyses, to the extent possible given our data, for X/Twitter, Instagram, and YouTube. X/Twitter looks exactly like TikTok: viewership is highly volatile, feeds are dominated by one-off hits from small accounts, and (to an even greater extent) very few creators make money. Instagram is similar in that most consumed content is produced by amateur accounts that do not make money, though it is somewhat more skewed towards large accounts and viewership is less volatile.[21]

YouTube looks very different: it is much more professionalized, with most consumed content making money for its creators. This is both because YouTube pays creators for viewership much more generously and because YouTube is more dominated by large creators with more stable viewership.[22] In this sense, YouTube is more similar to a TV channel that professionally subcontracts content production than to a social media platform. Consistent with the possibility that reliance on amateur content helps drive the pathologies of social media platforms, Appendix Figure A12 shows that only 10% of 18–30-year-olds we surveyed wish that YouTube did not exist, compared to more than 40% for each of Instagram, TikTok, and X/Twitter.

3.3 Motivating evidence on lifestyle and partisan content

The previous section established the presence of the basic patterns—dispersed viewer preferences, amateur-dominated production, local scarcity of appealing content—required for supply-side preferences to potentially influence social media consumption. We now zoom in on two specific content types: status-oriented lifestyle

[21] Unlike TikTok, Instagram has historically engaged in less algorithmic experimentation on small creators, which has been blamed for Instagram Reels' underperformance relative to TikTok (Instagram, 2024; TikTok, 2020). And unlike X/Twitter, Instagram is less reliant on sharing and reposting, the other mechanism for surfacing hidden gems from low-follower accounts.

[22] YouTube's equivalent of Creator Rewards pays out to channels above 1,000 subscribers (as opposed to TikTok's 10,000 follower requirement) and pays out for all videos (as opposed to TikTok's ≥ 1 minute restriction).

content and partisan political content. We (i) describe their prevalence in production and consumption, (ii) show that creators are selected on characteristics that predict posting of these content types, and (iii) exploit discontinuities in rewards for viewership to show that they are not produced to cater to viewer demand.

3.3.1 Descriptive statistics on production and consumption of lifestyle and partisan content

Content classification. We take samples of content *produced* and *consumed* on TikTok from the Research API and our viewership histories, respectively.[23] We scrape the posts' text and imagery and use LLMs to classify them according to a schema of content types described in Appendix C. We aggregate the detailed classifications into four broad categories depicted in Appendix Figure A18: *politics* (posts about political events or issues); *lifestyle* (posts visually emphasizing features of the creator's life, such as their appearance or routine); *stories/advice* (posts where a creator talks to the camera, relating a story, gossip, or advice); and *entertainment* (a broad category spanning comedy sketches, hobby demonstrations, edited montages, etc.).

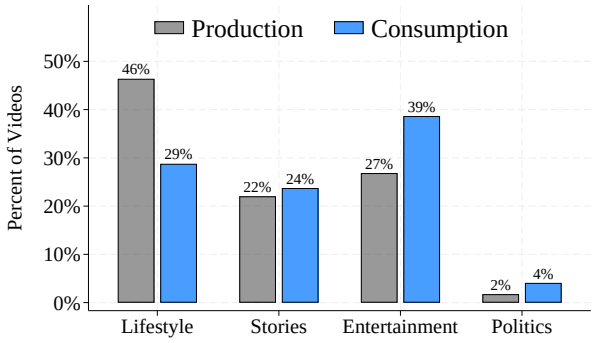

Lifestyle vs. entertainment. Panel (a) of Figure 7 plots the prevalence of these content types on TikTok. Our empirical investigation will focus on two objects: (i) the relative consumption rates of lifestyle and entertainment, and (ii) the intensive-margin partisanship of political content.

Panel (a) of Figure 7 shows that lifestyle content is produced more than it is consumed: it makes up just under 30% of consumed videos yet nearly 50% of produced videos. Conversely, entertainment accounts for nearly 40% of consumption but less than 30% of production. This is suggestive of a mismatch between viewer and creator preferences on the lifestyle-to-entertainment axis. Appendix Figure A17 shows that the lifestyle-to-entertainment consumption ratio is 0.74 on TikTok and 0.81 on Instagram, but only 0.21 on the more professionalized YouTube.

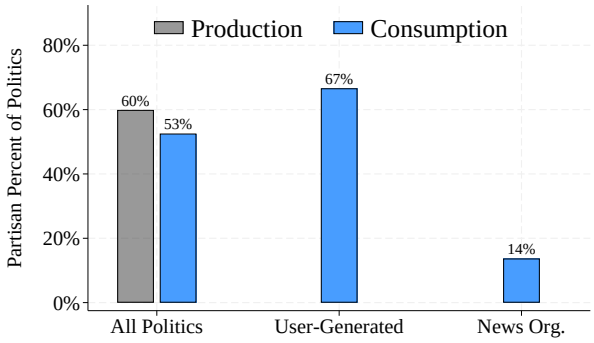

Partisanship of political content. Political content makes up just under 5% of viewers' feeds. This is slightly lower than the 8% of TV consumption going to political news according to Nielsen ratings and our own calculations (Appendix G). This is perhaps unsurprising given that social media viewers are much

Figure 7: *Content production, consumption, and partisanship on TikTok*

(a) *Production and consumption of content types*

(b) *Partisanship of political videos*

Notes: Panel (a) uses a random sample of videos created on TikTok from the Research API (production) and TikTok viewer histories (consumption) and plots the percent of videos falling into each of our four aggregated content categories, described in Appendix C. Appendix Figure A1 reproduces Panel (a), measuring consumption by weighting produced videos by their view counts instead of by using participants' histories. Panel (b) plots the percent of videos classified as being about politics that are classified as partisan, separately for created videos, history videos, and videos in histories that are versus are not posted by news organizations.

[23] An alternative way to measure consumption patterns is to weight the random sample of produced videos by their view counts. Appendix Figure A1 shows this produces nearly identical results.

younger than TV viewers. Appendix Figure A17 shows that politics is more common on Instagram (6%) and X/Twitter (10%) than on TikTok.

We will focus empirically on the intensive-margin partisanship of political content. "Partisan" videos are those tagged as expressing a clear partisan perspective; Appendix Figure A38 shows that partisan videos are also much more likely to be tagged as angry or contemptuous. Panel (b) of Figure 7 shows that 53% of consumed and 60% of produced political content is partisan. For comparison, we classify 65% of videos posted by Fox News's TikTok account as partisan, and 22% of viewership-weighted political TV news minutes as partisan (Appendix G). This means the average diet of user-generated political content on TikTok is about as partisan as Fox News, and consequently much more partisan than the average TV news diet.

About a third of political videos consumed on TikTok are posted by news organizations. Appendix G.2 shows that the partisanship of consumed political content is driven by user-generated videos. Partisan news outlets perform worse on TikTok than nonpartisan outlets: among both Democrat and Republican TikTok viewers, the most popular outlets for videos about American politics are the Daily Mail, CBS, NBC, and CNN. Videos posted by news outlets on TikTok are *less* partisan than their typical broadcasting, and, within outlet, nonpartisan videos receive more views than partisan videos. Viewers therefore seem to enjoy nonpartisan legacy news. However, such videos are scarce. As viewers scroll and the scarcity from Figure 6 Panel (b) kicks in, TikTok increasingly relies on user-generated political content. Overall, this pattern of results suggests the partisanship of consumed political content may be partly driven by amateur production.

3.3.2 Selection into content production

Figure 8 shows that the small creators dominating viewers' feeds are heavily selected, relative to the broader user population, on *enviability* and *ideological extremity*.

The figure draws on our survey of 3,490 users of Instagram, TikTok, X/Twitter, and YouTube. Respondents log in with their accounts, allowing us to scrape their account information and recent posts, which we link to two survey-elicited characteristics. "Enviability" averages responses to questions about how attractive the respondent is and how desirable other people would find their lifestyle. "Extremity" is the respondent's distance from the midpoint of a seven-point scale from "very liberal" to "very conservative."

Panel (a) shows that enviability positively predicts total posting volume on Instagram and TikTok, while ideological extremity predicts posting volume on Instagram and X/Twitter. (Heavy posters on the text- rather than image-based X/Twitter are *less* enviable than other users, consistent with certain stereotypes.)

Panel (b) shows that across platforms, enviable users are more likely to produce *lifestyle* content specifically, while ideologically extreme users are more likely to produce *political* content.

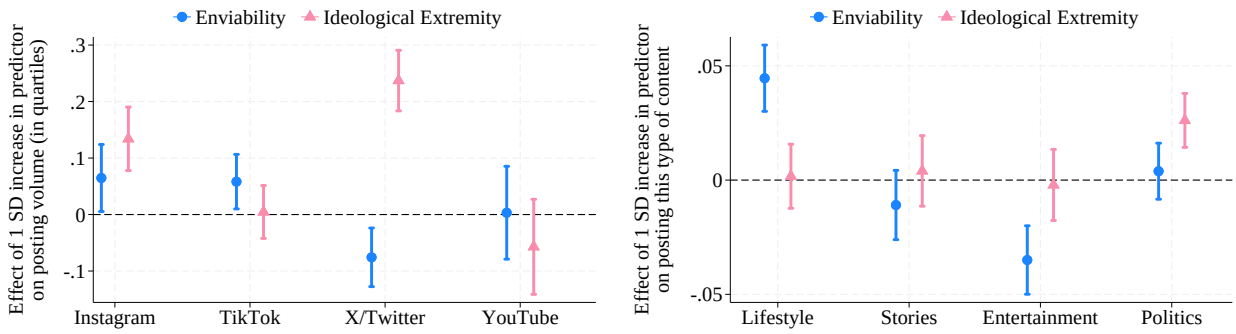

On YouTube—a highly professional platform as previously described—we do not observe these patterns.

Is selection driven by demand or supply? These patterns admit a supply-side explanation according to which enviable or partisan users derive more status or satisfaction from posting lifestyle or political content holding demand fixed. They also admit a demand-side interpretation according to which all creators pursue viewership, and enviable or extreme users expect their lifestyle or political content will attract more views.

Distinguishing between these possibilities is the central objective of our creator experiment in Section

Figure 8: *Selection into content production on social media*

(a) *Enviability and extremity predict total posting volume* ***(b)*** *Enviability predicts lifestyle, extremity predicts political*

Notes: Panels (a) and (b) use data from our survey of users of our four platforms of interest. Enviability is measured as the average response to two questions about self-rated attractiveness and lifestyle desirability. Ideological extremity is the distance from the midpoint of a 7-point self-reported ideology scale. Posting volume and the contents of recent posts are measured by requiring users to log in with their accounts, collecting their usernames, and scraping their accounts. Panels (a) and (b) plot the predictiveness of enviability and ideological extremity for total posting volume on a platform (conditional on being a user) and indicators for having recently posted specific content types, controlling for the number of posts we scrape. Appendix Figure A9 reproduces Panel (b) using the share of scraped posts of each type.

4.3, but our user survey provides a preliminary piece of evidence. For each of our video types, we ask 50% of respondents if they would be willing to *post* such a video on their account for $3. We ask the other 50% if for $3 they would be willing to privately *create* such a video and send it to us to be shown to a few other participants, but not post it. Willingness to perform the first task should be affected by expectations about the viewership such a post would receive, but willingness to perform the second task should only be influenced by the cost or enjoyment of producing such a video. Appendix Figure A10 shows that enviability and ideological extremity predict willingness to perform these two tasks with *equal* strengths.

3.4 Discontinuities in incentives to attract viewership

We close this section by providing one more piece of observational evidence that production of lifestyle and partisan political content is not driven by attempted catering to viewer preferences.

Institutional background. This evidence is presented in Figure 9, which shows systematic bunching in the production of different types of content at different video lengths. It exploits two facts.

First, TikTok's interface for filming videos offers default duration options of 15 seconds and 1 minute, as well as a normal "record indefinitely" button. After selection of one of the default options, the camera will start filming and stop automatically after 15 or 59 seconds unless manually stopped earlier. If creators using these default options tend to be *unsophisticated* producers whose content is not planned out, we should observe bunching of unsophisticated creators at and below 15 and 59 seconds.

Second, TikTok's Creator Rewards program—which pays eligible accounts with over 10,000 followers for views—pays out only for videos at least 60 seconds long.[24] So creators who are trying to maximize viewership in order to earn Creator Rewards payments should bunch at 60 seconds and above.

Summing up, if we sort videos by length and study their underlying creators, we should see a discontinuous increase in creator sophistication as we cross from 15 to 16 seconds and a discontinuous increase in

[24]This is presumably why the 60-second default recording option automatically stops at 59, rather than 60, seconds.

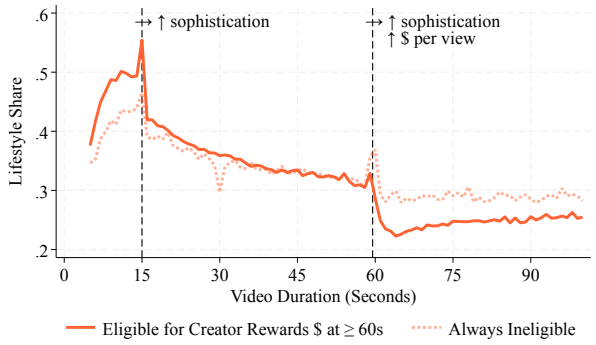

sophistication *and* financially-motivated attempts to cater to demand as we cross from 59 to 60 seconds.

Results. Figure 9 Panels (a) and (b) show that crossing these thresholds brings large, sharp decreases in the prevalence of lifestyle content and increases in the prevalence of entertainment. Panel (c) shows that the prevalence of partisan relative to nonpartisan political content is smooth across these thresholds. Appendix Figure A37 shows that emotions in political videos, such as anger and contempt, are also smooth.

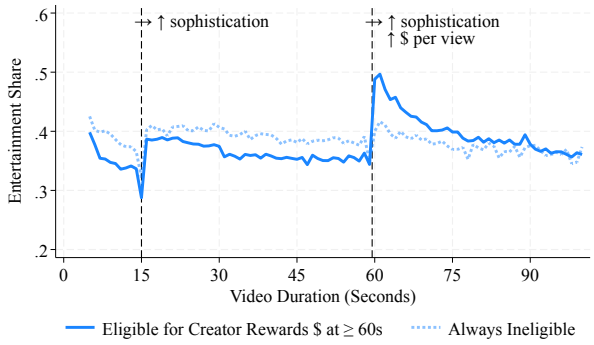

Two further results corroborate identification. First, only accounts with at least 10,000 followers are eligible for Creator Rewards. Figure 9 shows that the discontinuity at 60 seconds is much larger for such accounts. Second, Panel (d) shows that bunching of both video durations and content types is absent prior to, and appears rapidly in the months following, rollout of Creator Rewards in May of 2023.

Figure 9: *Lifestyle videos are posted by unsophisticated accounts with weak incentives to attract viewership; the opposite is true for entertainment*

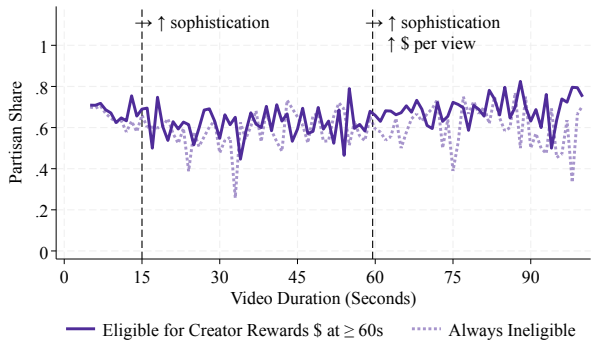

(a) *Lifestyle videos are posted by unsophisticated accounts with weak incentives to attract viewership*

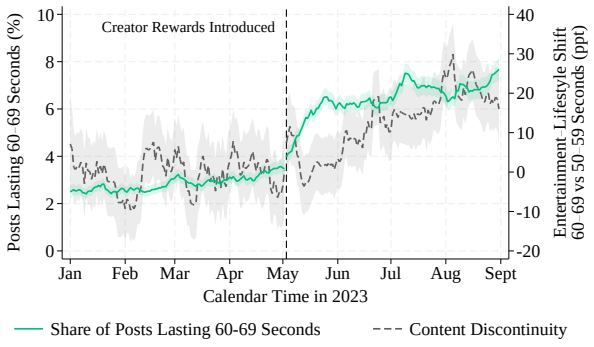

(b) *Entertainment videos are posted by sophisticated accounts with strong incentives to attract viewership*

(c) *Partisanship of political content does not vary with creator sophistication and financial incentives*

(d) *Bunching of video durations and content composition emerges after introduction of Creator Rewards*

Notes: This figure plots data from TikTok videos. To maximize precision we pool both videos randomly sampled from the Research API and videos in our viewership histories and use, for lifestyle and entertainment, predicted classifications from a classifier trained on our LLM codings. Appendix Figure A34 shows results separately by data source and by LLM versus predicted codings—all show the same patterns. The x-axis for the first three panels is the duration of the video in seconds. The y-axis shows the share of videos of this duration classified as lifestyle (Panel (a)) or entertainment (Panel (b)), or the share of political videos classified as partisan. Solid lines plot videos produced by accounts with at least 10,000 followers and shaded lines videos from accounts with fewer than 10,000 followers. Panel (d) uses data on videos produced during 2023 scraped from the Research API. It plots, over time, the share of videos between 60 and 69 seconds long (green line, left axis) and the entertainment-minus-lifestyle share gap when comparing videos 60-69 seconds long to videos 50-59 seconds long (black line, right axis). We use a 7-day rolling average on either side of the rollout date. Shaded regions show 95% confidence intervals.

Interpretation. Appendix F.4 develops the formal results underlying interpretation of these bunching patterns. If we assume that the cost of manipulating a video's length locally around 60 seconds is the same across content types, then under our model the changes in proportional prevalence plotted in Figure 9 identify rankings of content types according to expected viewership of pieces produced in equilibrium. In particular, the figure shows that entertainment has higher expected views than lifestyle, and partisan content does not have higher expected views than nonpartisan content.

Two caveats apply. First, the focus on discontinuous changes in content type *shares* is justified by our model's logit cost shocks. Under more general cost shock distributions, our inferences about viewership rankings will remain approximately valid when comparing content types with similar production shares (e.g., lifestyle vs. entertainment), but not when comparing types with different production shares (e.g., lifestyle vs. politics). Second, the discontinuities identify differences in expected viewership *among pieces produced in equilibrium*. We cannot distinguish whether lifestyle content attracts fewer views than entertainment because it enjoys less favorable latent demand or because creators enjoy producing lifestyle content more and are therefore willing to produce it down to lower levels of expected viewership. So these results identify either a demand-side force pushing against lifestyle or a supply-side force pushing for it.

Overall, neither lifestyle nor partisan content appears to be produced primarily to chase engagement. Instead, creators pursuing engagement opt for more effortful entertainment content.

3.5 Summary of observational evidence

This section has documented two sets of facts about content production and consumption on social media.

First, conditions are ripe for supply-side preferences to influence consumption: unpredictable viewer preferences prevent consolidation of viewership around professionals and create local scarcity of appealing content. Second, supply-side preferences—not attempts to chase demand—appear to specifically drive production of lifestyle and partisan political content.

4 Experimentally Disentangling Supply and Demand on Social Media

Section 3 presented observational evidence showing that conditions are ripe for supply-side creator preferences to influence consumption and directionally suggesting that the prevalence of two specific types of content—lifestyle and partisan political content—is driven by supply-side preferences.

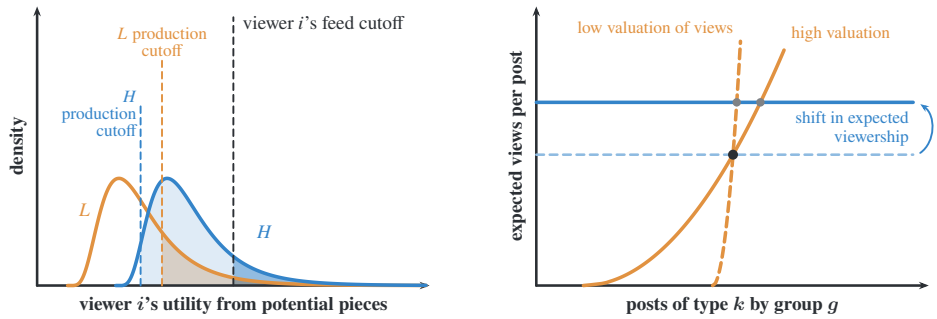

However, our observational data do not contain the variation necessary to estimate the parameters of our model and thereby quantitatively decompose the equilibrium prevalence of lifestyle and partisan political content into supply- versus demand-driven components. In this section, we conduct two experiments, one on the demand side and one on the supply side, to generate the variation necessary to estimate our model.

4.1 Identification

Proposition 1 established that equilibrium consumption of a given content type can be written as a function of two objects: the distribution of expected viewership of potential pieces of this type, which depends only

Figure 10: *Identifying supply and demand*

(a) *Demand-side identification challenge* ***(b)*** *Supply-side identification*

on demand-side preference parameters; and the distribution of creators' willingness to produce pieces of this type as a function of their expected viewership, which depends only on supply-side preferences.

Our goal in this section is to separately estimate the demand- and supply-side parameters underlying each of these objects. We now discuss the identification challenges we face in estimating these parameters.

Demand-side identification. Recall that a viewer's utility from a piece p of type k is $m_k + \widetilde{m}_{ik} + q_p + e_{ip}$. Within type k, creators belong to groups indexed by g, capturing heterogeneity in their ability to produce type k. We can write the quality of a piece of type k produced by group g as $\bar{q}_{kg} + \xi_p$, where $\bar{q}_{kg}$ is a scalar and ξ_p is drawn from some group-specific mean-zero distribution.

Our objective is to identify the fixed effects $m_k, \widetilde{m}_{ik}$ and the parameters of the distributions from which the q_p, e_{ip} shocks are drawn. The challenge we face in observational data, depicted in Figure 10 Panel (a), is a selection problem that operates on two levels.

The first problem arises if we look at the videos *in viewers' feeds*. Since the platform fills viewer i's feed with their favorites among produced pieces, pieces from lower-m content types will be more positively selected on $q_p + e_{ip}$ conditional on appearing in viewer i's feed. This means cross-type variation in engagement *within viewers' feeds* cannot be used to identify our parameters of interest.

Showing viewer i random videos sampled from the pool of all produced content fixes this problem. But the videos that are *produced* are still selected in a way that depends on supply-side parameters. If creators' taste μ_k for producing content type k is high, then even low-$\bar{q}_{kg}$ groups will opt into producing type k because doing so will still be worthwhile even at lower viewership. That is, the predictable quality cutoff above which it is worthwhile to produce will be lower for content types that creators enjoy producing.

To solve these problems, we need to measure viewers' utility from a set of pieces randomly sampled from the latent distribution of possible pieces of each content type. Average utility from each type then identifies m_k; the person-specific average deviation identifies $\widetilde{m}_{ik}$; and the joint distribution across viewers of residual utility identifies the distributions of q_p and e_{ip}.

Supply-side identification. Recall that a creator's utility from a produced piece of type k that receives v views is $\mu_k + \widetilde{\mu}_{jk} + \beta v^{\rho} + wv$. Our objective is to identify the fixed effects μ_k and $\widetilde{\mu}_{jk}$ and the coefficients β and ρ. The wage rate w is directly observed.

Identifying β and ρ requires measuring the sensitivity of supply to shifts in expected viewership, as

depicted in Figure 10 Panel (b). This is analogous to using demand-side instruments to shift prices and thereby identify supply elasticities in traditional markets. Our overall strategy will be to (i) measure total utility from posting; (ii) estimate the viewership utility parameters β and ρ using shifters of expected viewership; and (iii) obtain μ_k and $\widetilde{\mu}_{jk}$ by subtracting implied viewership utility from total utility.

Intuitively, in observational data we see that certain pieces are produced and we see how many views they attract. But we do not see the latent viewership of pieces that are not produced. We also do not see the extent to which produced pieces are inframarginal to production—would they still be produced at lower expected viewership? Identification requires filling in this missing information.

4.2 Demand-side experiment

Parametrization. We are interested in five content types: lifestyle, stories/advice, entertainment, partisan politics, and nonpartisan politics. We parametrize the components of u_{ip} as:

$$u_{ip} = m_k + \widetilde{m}_{ik} + \underbrace{\bar{q}_{kg} + \xi_p}_{q_p} + \underbrace{e^G_{G(i)p} + e^P_{P(i)p} + e^o_{ip}}_{e_{ip}} \tag{6}$$

e^G and e^P allow for commonality in the preferences of same-gender $G(i)$ and same-political-leaning $P(i)$ viewers. We assume that $\widetilde{m}$, e^G, and e^P are normally distributed with mean zero and type-specific variances, and e^o is drawn from a type I extreme value distribution shifted to have mean zero with a type-specific scale. The stochastic component of quality ξ_p follows a lognormal distribution shifted to have mean zero and has a type-specific variance and common shape.[25] We assume that across types, the shares of utility variance attributable to each of $\widetilde{m}$, q, e^G, e^P, and e^o are the same. All stochastic components are independent.

Within each type, we assume there are ten creator groups g that can be empirically approximated as follows. In the creator experiment described in Section 4.3, we ask creators whether they would be willing to produce a post of content type k in the next 24 hours for \$0.25. We assume a creator's group for type k can be approximated by their follower count (in five bins) crossed with whether they answer "yes" to this question. This is an approximation because a creator's willingness to produce type k on a given day is derived from the creator's primitive tastes and abilities plus today's realization of their k-specific cost shock. These shocks should wash out on average, though this will slightly attenuate our estimates of inter-group differences.

In our creator experiment, we randomly pay some creators \$10 to post content types they do not normally produce. We use these videos to estimate the latent quality of content from groups unlikely to produce in equilibrium. Because we have only 106 experimentally-induced posts, we cannot allow for arbitrary heterogeneity in the quality distributions of different groups. We therefore assume each unwilling-to-produce group faces a constant penalty δ_k to their quality relative to the willing-to-produce group in the same follower bin, and pool this parameter for lifestyle, entertainment, and politics.[26] This amounts to a moderate restriction on the shape of inter-group quality heterogeneity.[27] In our alternative demand estimates

[25] Appendix Figure A6 shows the four content types have very similar viewership distribution shapes.

[26] Because of variation in creators' willingness to post content types, our creator experiment generates 23 stories posts that creators were willing to produce absent payment versus 19 unwilling; but for lifestyle, entertainment, and politics, these are 16/4, 21/3, and 6/14, respectively, limiting the power of willing/unwilling comparisons.

[27] Consider a simple deterministic version of the model where creators' tastes for content type k generate a threshold $\underline{q}_k$ such that only groups g with $\bar{q}_{kg} > \underline{q}_k$ are willing to produce. ("Groups" here mean the actual primitive groups we approximate empirically.)

sourced from creators' expectations in the creator experiment, we do not impose this restriction, and Figure 13 shows that the two produce almost identical results.

Viewership experiment. The design and reduced-form analysis of this experiment were pre-registered on the AEA RCT Registry at AEARCTR-0019565 and are described in more detail in Appendix H.

Building a TikTok clone. We build a phone-browser-based clone of TikTok. We download real TikTok videos, host them on a server, and pipe them into users' feeds. Appendix Figure A40 shows a screenshot of the clone and it can be scrolled through (on a phone) at this link: `https://feed-demo.mitsocialmediastudy.com/`. It reproduces all of TikTok's main features: viewers swipe at their leisure through an infinite vertical feed, and they can "like" a video, tap to open the top comments or expand the caption, or copy the video's URL to share it with a friend. We record every aspect of users' behavior, including how long they watch a video, whether they "like" it, whether they open its comments or expand its caption, and so on.

Sampling videos. We randomly sample 260,000 videos posted in the days preceding the experiment using TikTok's Research API, classify them, and select a stratified subset covering our four content types, yielding 1,900 politics videos and 5,000 videos each for lifestyle, entertainment, and stories/advice. We also scrape 400 videos recently posted by the 100 news organizations appearing most commonly in the feeds of participants who donated their TikTok viewership histories. Finally, we add 106 videos, including at least 20 of each type, whose creation we induced by paying a participant in our creator experiment $10 (described next section).

Each viewer receives a feed of videos randomly drawn from this pool, stratified by content type.[28]

Recruiting viewers. We recruit Americans aged 18-30 from Prolific, verifying their status as TikTok users by requiring them to log in with their account to enter the experiment. After login, 624 participants start the experiment and 586 complete it. Appendix Figure A41 shows that attrition is not predicted by the content early in a person's feed and that including incomplete sessions does not affect our results.

Our sample includes 94 participants who had earlier donated their viewership histories; for these participants, we include in their experimental feeds several dozen videos recently posted by creators who appeared regularly in their personal history, and use their engagement with these videos for an overidentification test.

Experimental flow. Once a participant enters the experiment, we explain its procedures. We tell them they will scroll through videos for 20 minutes, and should behave as they ordinarily would on TikTok, swiping past videos they dislike and watching ones they like. We incentivize genuine engagement by telling them they may be invited back to a future scrolling session, and we will use their engagement behavior in the first session to design a personalized feed for the session just like the TikTok algorithm would operate. To ensure respondents actively watch and scroll, we randomly flash several attention checks throughout the 20-minute window that respondents must tap within a few seconds of their appearance in order to receive their payment.

The restriction we impose is twofold. First, within each type k the distribution of $\bar{q}_{kg}$ is such that for varying values of q near $\underline{q}_k$, $\mathbb{E}(\bar{q}_{kg}|\bar{q}_{kg} > q) - \mathbb{E}(\bar{q}_{kg}|\bar{q}_{kg} \leq q)$ is constant. For example, this will be satisfied if the local distribution of $\bar{q}_{kg}$ across creators is uniform. Second, the variance of $\bar{q}_{kg}$ across creators is the same for each k. Importantly, we still allow the supply-side parameters determining $\underline{q}_k$ to vary across types. Under these restrictions, $\underline{q}_k$ affects the share of creators falling above the threshold but not the average quality gap between above- and below-threshold creators.

[28] The shares of lifestyle and political content in a viewer's feed are drawn independently from $\{0, 0.1, 0.2, 0.3\}$ with probabilities $\{0.2, 0.2, 0.4, 0.2\}$. Residual videos are split equally between entertainment and stories, with 5% reserved for non-political videos posted by news organizations. Political videos are stratified to be 80% user-generated and 20% posted by news organizations.

After 20 minutes of scrolling, we present the respondent with 5 pairs of videos they saw and ask them to indicate which they liked more. Comparing their choices to their prior engagement behavior lets us measure behavioral noise. Finally, participants answer a few demographic questions.

Model of engagement. Identifying utility parameters from viewers' engagement behavior requires a model linking engagement to utility and accounting for the fact that decisions to swipe past a video are endogenous to the viewer's outside option of watching the next video. We assume that when viewer i swipes into video p, her flow utility of watching it starts at $u_{ip} - \gamma h_{ik}$, where h_{ik} is the share of already watched videos that are of the same type. We assume her utility declines linearly at rate a as she continues watching. Opportunities to consider swiping to the next video arrive as a Poisson process with rate r_i. When an opportunity arrives after t seconds, she compares $u_{ip} - \gamma h_{ik} - at + \nu_{ip}$, where ν_{ip} is a behavioral noise term, to her value of starting the next video V_i minus a swiping cost c_i, and decides whether to swipe.

A more parsimonious engagement model could be written but would struggle to fit observed engagement behavior, which exhibits several patterns: (i) viewers vary systematically in how rapidly they drop out of watching a video; (ii) about 40% of videos are swiped past within the first two seconds; (iii) conditional on watching two seconds, viewers exit gradually rather than always finishing the full video.

Identification. Figure 11 Panel (a) summarizes how each parameter in Equation (6) and our engagement model is identified from experimental engagement behavior. Intuitively, viewers' average taste for a content type is identified from their average watch time when encountering a video of this type. Variances of vertical quality and horizontal fit are identified through the covariance matrix across viewers of taste for videos within each type. And diminishing returns within type are identified from our extensive-margin randomization of the share of a viewer's feed drawn from each type. The engagement model parameters are identified from the shapes of watch time distributions: the reconsideration arrival rate r_i is identified from the earliest times a participant is observed swiping past videos, the swiping cost c_i is identified from a participant's average watch duration, and a is identified from the slope with which participants gradually exit videos.

Estimation. Estimation of the model proceeds in three steps. First, we normalize the mean utility of entertainment to zero and the variance of the stochastic component of utility across all pieces to 1. Second, we fit the viewer-specific engagement parameters r_i, c_i and average utilities by content type to observed viewership behavior by maximum likelihood. Third, we split the residual variance of utility into its components by maximizing the joint likelihood of the engagement behaviors of different participants seeing the same videos.

Reduced-form results. Figure 11 Panel (c) shows results for one of our pre-registered engagement measures: the probability that a viewer watches at least 10 seconds of a video. Our other pre-registered measures, which produce consistent patterns, are plotted in Appendix Figure A42.

Three patterns are evident. First, lifestyle content suffers a substantial demand penalty: it is the least engaging type. This includes lifestyle videos our classifier tags as "enviable," meaning they feature an unusually attractive or wealthy focal person. Partisan political content, particularly content concordant with a viewer's ideology, is more engaging than non-partisan content, but this effect is modest in size.[29]

[29] Our discontinuity-based evidence suggested no demand premium for partisan content. This discrepancy is partly explained by the fact that our experimental participants are more politically partisan than the general population of TikTok users. Appendix Figure A44 shows that re-weighting accordingly shrinks the experimental partisanship premium, but only very slightly. This suggests our

Second, differences in engagement rates across types are small, with a substantial minority of videos of each type engaging viewers. For example, 21% of entertainment videos, the most engaging type, are watched for at least 10 seconds, while the figure is 15% for the least engaging type, lifestyle. This is consistent with high-variance within-type quality and taste shocks causing even content types with lower baseline appeal to regularly produce pieces with sufficiently high shock draws to interest viewers. This amplifies the importance of supply: if lifestyle videos are on average 25% less likely than entertainment videos to engage a viewer enough to enter their feed, a 33% supply advantage would suffice to make lifestyle videos appear in viewers' feeds more commonly than entertainment.

Modest variation in engagement rates could result from genuine preference dispersion or from noisy behavior. We separate the two with the end-of-experiment module where we ask participants to retrospectively indicate which video they preferred out of five pairs they saw. Respondents affirm their earlier revealed preference in 84% of cases. Assuming the 16% disagreement rate reflects noise in engagement behavior (rather than gaps between revealed and stated preference), we conduct an empirical Bayes procedure to disattenuate engagement differences across types. Appendix Figure A43 shows this barely changes results.

Third, note that if content production primarily caters to demand, videos produced in equilibrium should engage viewers substantially more than videos not produced in equilibrium. By contrast, if there is important variation in supply-side preferences, some videos may not be created in equilibrium despite facing high latent demand because they would be difficult or unsatisfying to create. The green bars in Figure 11 Panel (c) show that when we pay a participant in our experiment $10 to produce a video of a type they were *unwilling* to produce for $0.25, these videos receive just as much engagement on average as videos participants *were* willing to create for $0.25, and just as much as actual scraped videos. This suggests variation in production is driven by supply- rather than demand-side preferences, a conclusion our creator experiment affirms.[30]

Parameter estimates. Panel (b) of Figure 11 shows estimates of our key utility parameters. Results line up qualitatively with Panel (c), though stories/advice looks worse because the parameter estimates exploit richer variation in engagement than whether videos are watched for at least 10 seconds.

Two conclusions are again evident. First, entertainment is the highest-utility type, lifestyle is the lowest, and partisan political content enjoys a modest advantage over nonpartisan content. Second, residual preference dispersion is large enough to substantially attenuate the effects of variation in average appeal. For example, the normalized utility gap between entertainment and lifestyle is 0.56, but a single standard deviation of vertical quality q or half a standard deviation of idiosyncratic appeal e each almost suffice to overcome this mean disadvantage. Our results imply that the posts appearing in a viewer's feed are about 6.7 standard deviations of appeal above the average entertainment post, and lifestyle posts are about half as likely as entertainment posts to clear this threshold. This means that, all else equal, lifestyle posts would only need to be produced twice as much as entertainment to appear in feeds at higher rates.

Simulating consumption. We can use our demand estimates to simulate the distribution of consumption given the observed distribution of production across content types and account sizes. Generating this

experiment if anything *overestimates* the demand advantage of partisan content.

[30] Marginal created and uncreated videos within a type should experience equal viewership, but the blue bars in the figure capture average inframarginal engagement with created videos, and the second green bar captures average engagement with uncreated videos down to $10 below the creation threshold.

Figure 11: *Viewership experiment: identification, viewer utility parameters, engagement, and simulated consumption*

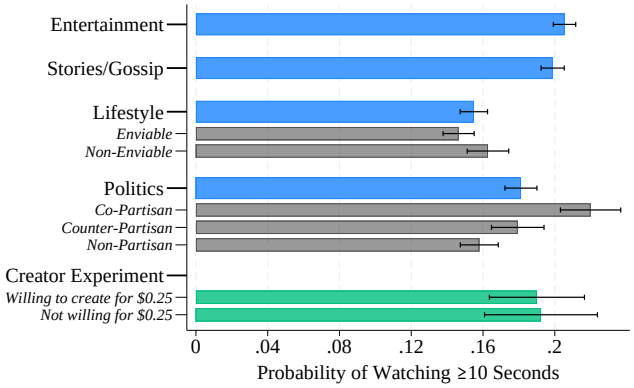

(a) *Identification of viewer utility parameters*

Parameter	Variation that identifies it
Mean appeal m_k	Average engagement with videos of this type.
Variance of $\widetilde{m}_{ik}$	Cross-viewer variation in average engagement with this type.
Group-specific part $\bar{q}_{kg}$ of q_p	Average viewer engagement with videos of this type created by the relevant group, using videos induced by our creator experiment from creators who do and do not regularly produce this type.
Variance and shape of stochastic part ξ_p of q_p	Cross-video engagement variation that is correlated across viewers.
Variance of e_{ip}	Shared components: within-video within-demographic-group correlation in engagement. Residual component: remainder after partialling out other components of utility and noise.
Diminishing marginal utility γ	How engagement with a type declines with its randomized share of the viewer's feed.
Engagement model (experiment only)	
Swiping costs c_i	Variation in viewers' average viewing times.
Within-video boredom a	Slope with which viewers gradually exit videos conditional on staying past the likely arrival of a reconsideration opportunity.
Reconsideration rate r	The earliest times that different viewers swipe past videos.
Variance of noise ν_{ip}	How often viewers re-pick the video they engaged with more in the re-pick module.

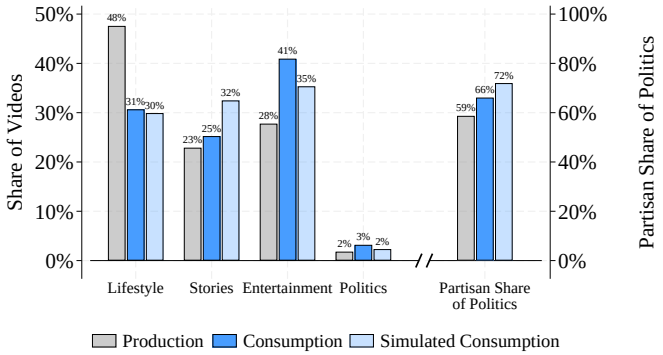

(b) *Parameter estimates*

Parameter	Estimate	SE
Mean appeal m_k, relative to entertainment		
Lifestyle	−0.56	(0.06)
Stories	−0.26	(0.15)
Co-partisan politics	0.14	(0.09)
Counter-partisan politics	−0.12	(0.08)
Nonpartisan politics	−0.17	(0.09)
Standard deviations of shocks		
Quality q_p	0.42	(0.02)
Idiosyncratic appeal e_{ip}	0.91	(0.01)

(c) *Probability of watching ≥ 10 seconds by content type*

(d) *Production, consumption, and simulated consumption of content*

Notes: Panel (a) explains how each viewer utility parameter is identified from our viewership experiment. Panel (b) displays estimates of the parameters of the viewer utility function from our experiment, with bootstrapped standard errors. Panel (c) plots the average probability that a viewer watches a video of each type for at least 10 seconds, calculated from regressions controlling for viewer, sampling-source, and video-duration-decile fixed effects. Panel (d) plots, for each of our content types, the type's observed share of *production* (measured by randomly sampling from produced videos using TikTok's Research API), its observed share of *consumption* (measured from the viewership histories of our participants), and its *simulated* share of consumption, obtained by taking the observed pool of produced content and applying our model-derived demand estimates to it. In Panel (d), we restrict to user-generated political content, excluding news organizations.

simulation requires one more step: estimating the utility threshold above which videos appear in viewers' feeds. We calibrate this to the probability that a video we randomly sample from TikTok's Research API appears in a given participant's viewership history (about 1 in 44,000).

Figure 11 Panel (d) shows results. Despite using only experimental variation, our demand estimates closely reproduce actual consumption patterns. This is our first and most important overidentification test.

Other fit and overidentification tests. Appendix H describes and shows results of our other fit and overidentification tests. Our model closely fits experimental watch-time distributions and variation in watch times across content types. Moreover, its predictions pass a series of overidentification tests in our observational data. A video's demand estimate in our experiment is highly predictive of how many views it ends up receiving on TikTok. Our demand estimates plus assumptions about feed-membership cutoffs also reproduce participants' experimental engagement with videos from creators who appear regularly in their actual TikTok histories, and the relationship between videos' age and their prevalence in viewer feeds.

Demand estimates from creators' expectations. An alternative approach to estimating the latent distribution of demand for content is to ask each creator j about their subjective probability distribution over the views they would receive if they created a piece of content of type k. We approximate this in our creator experiment, described below, by asking creators incentivized questions about their average expected viewership if they created content of different types. These viewership expectations do not let us cleanly separate demand into components stemming from the different primitives m_k, q, e^G, e^P, e^o, and so on, but they are sufficient statistics for the decompositions and counterfactuals we conduct in Section 4.4. Appendix Figure A7 repeats the overidentification test from Figure 11 Panel (d) using these expectations and shows that these expectations-sourced demand estimates reproduce observed consumption from observed production about as well as demand estimates sourced from our viewership experiment.

4.3 Supply-side experiment

Our supply experiment elicits creators' willingness to post different content types and their expectations about and valuation of viewership, to disentangle intrinsic supply-side tastes from attempts to chase viewership.

Recruitment. We recruit 979 Prolific users aged 18-30 who have posted at least once before on TikTok, as verified by logging in with their account. The median participant has 160 followers and 16 historical posts, while the average participant has 1,755 followers and 88 posts. Appendix I shows that our lifestyle results are robust to restricting to the 19% of participants with at least 1,000 followers, while our politics results become very noisy in the smaller sample because political posting is rare. We also show that our results are qualitatively consistent with descriptive results from our creator survey (Figure 5 Panel (b)), which has a sample representative of the distribution of creators that viewers see on TikTok. As pre-registered, we re-weight responses to match the observed distribution of TikTok production.

Experimental design. The experiment, weighting scheme, and reduced-form analyses were pre-registered on the Open Science Framework at `https://osf.io/24tcz`. See Appendix I for further details. The survey can be clicked through at `https://demo.mitsocialmediastudy.com/`.

The flow of the experiment is depicted in Appendix Figure A51. Participants complete a survey about content creation on TikTok. We begin by explaining that it is incentive-compatible to answer all questions truthfully, link participants to the full implementation procedure, and tell them they are guaranteed to receive a paid posting offer at the end of the survey. We then define the four content types we will ask about, and provide definitions, examples, and links to videos in each category, randomly sampled from our history data.

The first section elicits participants' baseline willingness to accept to post different content types and their expectations about viewership. We start with a binary question: for each content type, would you be willing to make a post of this type on your account in exchange for $0.25? We then elicit incentivized expectations about how many views the post would receive. To enable supplementary analyses, we also elicit participants' willingness for $0.25 to privately *create*, but not post, a video of this type and send it to us to be shown to other participants. We also ask two questions probing the reasons behind participants' answers.

Next, we elicit respondents' scalar willingness to accept to post each type. For respondents *un*willing to post for $0.25, this is the minimum payment they would need to be offered to agree to make a post of this type. For respondents *willing* to post who indicate they were planning to make a post of this type anyway, we elicit the minimum payment they would require to *abstain* from making posts of this type on their account for the next week. (Since we have their account details, we can enforce this.) We divide their willingness to accept by their average number of posts of this type in weeks where they make at least one, to calculate a per-post willingness to pay to continue posting.[31] Our offer generation procedure ensures responding truthfully at each step in this sequence is incentive-compatible; essentially, the procedure is a BDM mechanism and we use a participant's responses to construct a scalar willingness to accept that can either be positive or negative.

The second section measures valuation of viewership. For each content type, we tell participants that if we offer them a payment high enough to induce a post of this type, we may offer them an intervention intended to boost their viewership for that post. We randomly offer one of two interventions: a payment to boost their post algorithmically (an option TikTok offers), or tips from a professional content creator. Insofar as the latter also boosts their viewership on future posts, we should overestimate participants' marginal valuation of viewership. We elicit participants' willingness to pay for this intervention and their incentivized expectation about its effects on viewership.[32] Their willingness to pay for the intervention divided by their expectation about its effects captures their marginal valuation of viewership. To measure their full viewership valuation function βv^{ρ}, we estimate ρ by asking participants to indicate indifference points between various increments of views starting at different viewership levels. For example, we ask: "starting at 1,000 views, how many additional views would a creator need to get so that their satisfaction from this increase in viewership matches the satisfaction of going from 0 to 100 views?" This last object is the only one that is not incentivized.

At the end of the survey, each creator is randomly offered a payment to produce a certain type of content. With 1% probability this offer is drawn based on the BDM mechanism that makes truthful responding

[31] We do this by scraping their historical posting behavior. This may underestimate their true valuation if they would simply postpone these posts until after the week ended. Appendix Table A15 shows that results are robust to restricting to creators who report that they would not make these posts at all, and to manually inflating valuations in these arms to account for potential underestimation.

[32] For 50% of respondents, this is an unincentivized question about its expected effects on their own viewership. (This cannot be incentivized because we would not observe both potential outcomes.) For the other 50%, this is an incentivized question about its expected effects on the viewership of other participants, where aggregating across multiple participants lets us construct this estimate. Appendix Table A16 shows results are robust to restricting to either group.

incentive-compatible. With 99% probability it is a $10 offer to produce one of our four content types, drawn at random. This is because the goal of these offers is to induce creation of videos for use in our viewership experiment. We began by setting equal draw probabilities for each of the four content types and, as data collection progressed, adjusted these probabilities to try and balance created videos across the four types. 33% of respondents indicate an intention to accept the offer and one-third of these 33% end up submitting a video. We end up with 20 lifestyle, 24 entertainment, 42 stories, and 20 politics videos.

Parametrization and identification. Recall that creator j's payoff from creating a piece of type k which ends up receiving v views is $\pi_{jk} = \mu_k + \widetilde{\mu}_{jk} + \beta v^\rho + wv - \kappa_{jk}$. We assume that κ_{jk} is drawn from a type I extreme value distribution with the same scale for each content type. To map the experiment into our static model, we assume that a period in the model corresponds to a 24-hour period, so the willingness-to-accept answers covering the next 24 hours represent one-period utilities. We also assume that when creating political content, self-identified ideologically moderate creators produce nonpartisan content and creators with ideological leanings produce partisan content. As pre-registered, we re-weight creators so that the distribution of production implied by their responses matches the observed distribution of production on TikTok. Since our objective is to *decompose* observed production into components driven by different rewards rather than to reproduce observed production, this re-weighting is innocuous. It implicitly imposes a conditional independence assumption: that conditional on follower count and observed posting, creators in our experiment are representative in terms of supply parameters of actual creators on TikTok.

Identification of parameters is simple and summarized in Figure 12 Panel (a). A creator's overall willingness to accept to create a post captures their overall utility from that post π_{jk}. Their viewership-valuation parameters β and ρ are estimated from their marginal valuation of viewership and indifference responses; combining these with their expected viewership and Creator Rewards eligibility yields their reward from viewership $\beta v^\rho + wv$. Subtracting this out of their overall willingness to accept yields $\pi_{jk} - \beta v^\rho - wv = \mu_k + \widetilde{\mu}_{jk} - \kappa_{jk}$. Calibrating to the creator's observed historical posting behavior yields the scale of κ_{jk}.

Complexity. The experimental elicitation procedure is complex. And we estimate creator preferences via a residualization: we ask how much of observed variation in willingness to post remains after subtracting out the product of expected viewership with implied valuations of viewership. Classical measurement error in the latter will not bias our results because it enters additively. But a natural worry is that some form of non-classical response noise on the right-hand side may bias our results. Our approach is to corroborate our parameter estimates with simple, transparent supplementary quantitative and qualitative results.

Results. Parameter estimates are displayed in Figure 12 Panel (b). We estimate them in two independent steps. First, we estimate an average ρ across creators by fitting creators' viewership indifference responses by least squares, and β using creators' willingness to pay for, and expectations about the effects of, the viewership interventions. Second, we estimate each creator's total expected utility from posting each content type, plus the scale of the cost shocks κ, by fitting creators' willingness to accept answers from the survey and their historical posting frequencies by maximum likelihood. Subtracting results from the two steps, and using information about wages imputed from creators' follower counts, separates $\beta v^\rho + wv$ from $\mu + \widetilde{\mu}$.

There is substantial variation in willingness to post across content types: the median gap in willingness

to post between types a creator is willing to post for \$0.25 versus types they are not is \$23.33. But the median gap in implied utility from viewership is only \$0.64, suggesting that almost all of the variation in willingness to post is driven by variation in supply-side parameters rather than expectations about viewership.

Two facts drive this. First, the gap in average expected viewership between content types respondents are versus are not willing to post is small: 813 versus 666 views, or 22%. Appendix Figure A52 shows that when paid to post different content types, creators actually get slightly *higher* (albeit imprecisely estimated) viewership for types they were initially unwilling to post.

Second, participants' marginal valuation of viewership—median of \$0.23 per 100 views—is small. This is not because creators do not care about viewership. Panel (b) shows that for the median post creators are willing to make for \$0.25, their implied payoff from viewership is \$9.47 while their overall utility is \$5.00, indicating a \$4.47 cost of producing and posting the video. Rather, it is because returns to viewership are strongly concave, with an estimated $\rho \approx 0.3$, meaning viewership is not that valuable *on the margin*.

Such concavity is consistent with scope-insensitive satisfaction from attention: the first few dozen views or likes are exciting, but after that, a creator's ability to psychologically differentiate between the attention from 200 views and the attention from 500 views is limited. Our qualitative interviews (Appendix Table A19), which ask creators open-ended questions about why they enjoy posting, suggest four additional reasons for concavity. First, many creators report deriving most of their satisfaction from small-scale, two-way interactions with small communities of commenters and viewers who regularly return to their posts. Second and similarly, early views tend to come from friends or consistent followers whose attention the creator values, while later views come from strangers who matter less. One interpretation is that many creators post in pursuit of small-scale bilateral social connection, and the price they pay for accessing a platform that facilitates those connections is that the platform occasionally distributes their posts more widely to entertain other viewers. Third, many creators only pay attention to a post for a short while after it is posted and therefore only attend to the first few views and likes. Fourth, several creators report deriving most of their satisfaction from simply knowing that at least some people like what they posted.

Concave rewards from attention are consistent with a large body of work in psychology on diminishing returns to social rewards (Eisenberger, 1970; Ren et al., 2022). They are also consistent with prior work on social media. Srinivasan (2024) studies TikTok creators whose posts go unexpectedly viral and finds a subsequent increase in production that is almost completely insensitive to the size of the virality shock—the effects of receiving 100 likes and receiving 3,500 are indistinguishable. He interprets this as evidence of extremely concave returns to viewership. Outside of economics, Lindström et al. (2021) and da Silva Pinho et al. (2024) find similar results using the same strategy and Scissors et al. (2016) find similar results when surveying Facebook users about satisfaction from receiving "likes."

Supporting evidence. Three additional facts corroborate the result that expectations about viewership play little role in explaining variation in willingness to supply different types of content. First, as Figure 12 Panels (c) and (d) show, willingness to *post* a content type is strongly correlated with willingness to privately *create* it, replicating Appendix Figure A10's implementation of the same exercise in our user survey. The panels show that enviable creators are substantially more willing to post lifestyle content, but *also* substantially more

Figure 12: *Creator experiment: identification, creator payoff parameters, and drivers of willingness to post*

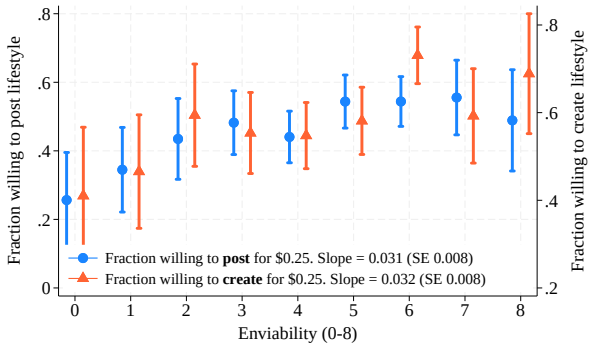

(a) *Identification of creator payoff parameters*

Parameter	Variation that identifies it	Data source
Mean taste μ_k	Average willingness to accept to post this type, partialling out the value of expected views βV^ρ.	Experiment.
Deviations $\widetilde{\mu}_{kg}$	Group-specific m deviations from overall creator average.	Experiment.
Expected views V	Expected viewership for a post of this type.	Experiment.
Value of views β	WTP for the view-boosting intervention, incentivized expectation of its effect on viewership ΔV, expected baseline viewership, and curvature: $\text{WTP} = \beta\left[(V+\Delta V)^\rho - V^\rho\right] + w\Delta V$.	Experiment.
Wage per view w	Creator follower count plus public information about Creator Rewards rates.	Experiment.
Curvature ρ	Answers to the indifference questions.	Experiment.
Variance of κ_{jk}	Calibrated to match creators' actual posting histories given their Experimental answers.	Experiment. & posting histories
Group masses ω_{kg}	Share of creators in each follower bin who do and do not regularly post the type, with a pre-registered weighting procedure that matches the actual distribution of TikTok production.	Experiment. & Research API

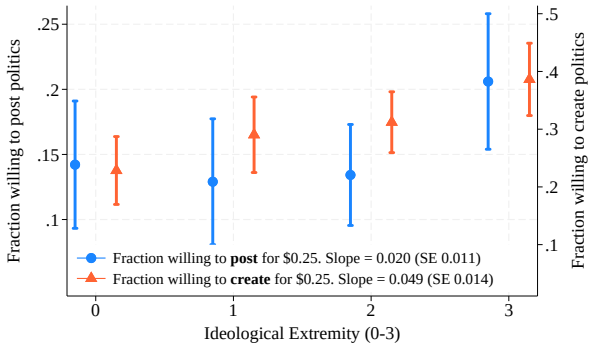

(b) *Creator payoff parameter estimates*

Parameter	Estimate	SE
Mean taste μ_k, % relative to entertainment		
Lifestyle	8.8	(1.5)
Stories	−16.0	(3.4)
Mean taste μ_k, % relative to nonpartisan politics		
Partisan politics	35.3	(8.5)
Value of views β	1.20	(0.09)
Curvature ρ	0.33	(0.005)
Expected views, creators willing to post only some types		
Types willing to post for $0.25	813	(48)
Types not willing to post for $0.25	666	(47)
Expected views, % relative to entertainment		
Lifestyle	−32.5	(2.1)
Stories	−25.3	(2.2)
Expected views, % relative to nonpartisan politics		
Partisan politics	53.7	(15.5)
For the median planned post		
Total utility from post	$5.00	(0.69)
Utility from viewership	$9.47	(0.77)
Utility from first 100 views	$5.55	(0.40)

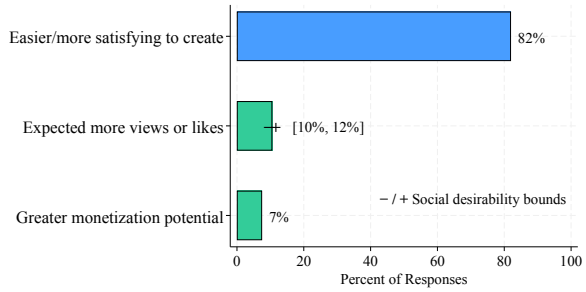

(c) *Willingness to post lifestyle by enviability*

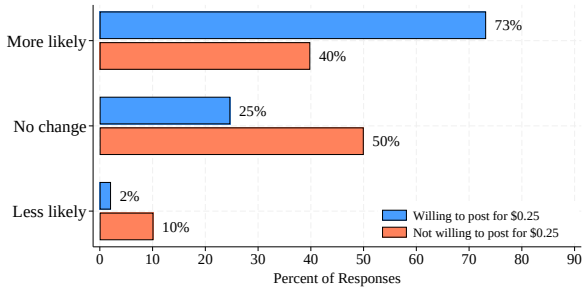

(d) *Willingness to post politics by extremity*

(e) *Why were you willing to post content type A for $0.25 and not type B?*

(f) *If your expected viewership from this type doubled, how would this change your likelihood of posting it?*

Notes: Panel (a) explains how creator utility parameters are identified and Panel (b) shows parameter estimates and bootstrapped standard errors. Panels (c) and (d) show the shares of creators willing to post or privately create a lifestyle or political video for $0.25, separately by their self-reported enviability in the case of lifestyle or ideological extremity in the case of politics. Panel (e) shows the percent of creators selecting each of three multi-choice options in response to a question about why they were willing to post some content types for $0.25 and not others (asked to all creators for whom that was true). Panel (f) plots responses to a question we ask separately by content type: hypothetically, if the viewership a creator expected for posts of this content type doubled, how would this change their likelihood of posting this type. We split responses by whether this was a type the creator was versus was not willing to post for $0.25.

willing to privately create such content. The same is true for ideologically extreme creators and political content. Respondents' binary willingness to post and willingness to create agree in 73% of cases.[33]

Second, we ask respondents a qualitative question about why they were willing to post certain types for \$0.25 but not others. Figure 12 Panel (e) shows that 82% of respondents say this is because "creating posts of [certain types] would be easier or more enjoyable, or [I] would be more comfortable posting them," rather than because they expect those posts would attract more likes and views. We randomize the wording of the latter option to manipulate its social desirability as detailed in Appendix Figure A54, which changes answer rates by only one percentage point despite successfully flipping perceived social desirability.

Third, for each content type, we ask respondents to imagine that their expected viewership for this content type doubled. We ask whether this would make them more likely to post content of this type. Figure 12 Panel (f) shows that for content types respondents were already willing to post, 73% say yes. For content types respondents were *not* willing to post, only 40% say yes, and 10% say this would make them *less* likely—concentrated among ideological moderates asked about posting political content, who are evidently uncomfortable having others see their political content.

The main result of the experiment—that variation in willingness to supply different types of content is mostly driven by variation in the costs or expressive benefits of production, rather than expectations about demand—is therefore corroborated by several supplementary pieces of evidence. It is also corroborated by our representative survey of TikTok creators, which showed (Figure 5 Panel (b)) that supply-side considerations are rated as being much more important than expectations about viewership in determining production choices, and that this is robust to a social-desirability wording manipulation (Appendix Figure A31).

4.4 Quantification

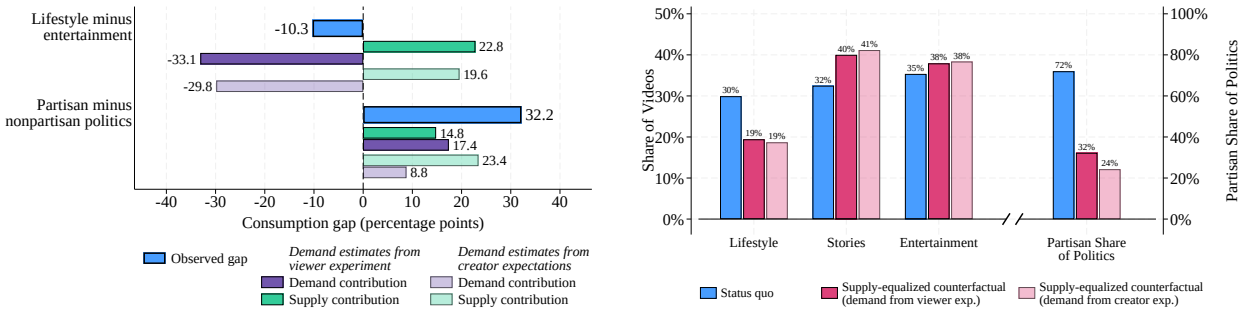

We now combine our demand- and supply-side parameter estimates and conduct decompositions and counterfactual exercises. We have two sources of demand-side information. First is our viewership experiment, which yields estimates of utility parameters for each content type. Second is our creator experiment, which collects creators' expectations about viewership for each type of content they could potentially produce. We can therefore show robustness of our results to using either source of demand-side information.

Panel (a) of Figure 13 conducts Oaxaca decompositions on two objects of interest: the gap in equilibrium consumption between entertainment and lifestyle content, and the gap between partisan and nonpartisan political content. The decompositions operate by asking how much consumption would change if we reassigned one content type to have the other's supply (or demand) parameters and mechanically recalculated consumption without accounting for factors like diminishing marginal utility from a given content type. As expected given the directions of our demand estimates, the gap in consumption between entertainment and lifestyle content reflects a strong supply-side force favoring lifestyle content colliding with a strong demand-side force favoring entertainment. Meanwhile, the gap between partisan and nonpartisan political content is between half and two-thirds explained by a supply-side force favoring partisan content, with the rest explained by demand favoring partisan content.

[33] Participants are in general more willing to privately create these content types for \$0.25 than to post these content types. One way to make sense of this is that creating a video yields expressive satisfaction that outweighs creation costs, while publicly posting a

Figure 13: *Oaxaca decomposition of observed consumption gaps, and counterfactual consumption rates after equalizing supply parameters*

(a) *Decomposition of consumption gaps into supply and demand* ***(b)*** *Consumption with supply-side parameters equalized*

Notes: Panel (a) displays a Oaxaca decomposition of observed gaps in consumption rates between lifestyle content and entertainment content, and between partisan and nonpartisan political content, into a supply contribution (how different would consumption rates look if we equalized both types' demand parameters?) and a demand contribution (how different would they look if we equalized supply parameters?). We plot two versions of the decomposition, one using demand estimates calculated from our viewership experiment and the other using creators' expected views from our creator experiment. Panel (b) displays, in blue, the "status quo" distribution of consumption simulated from our model using creator-experiment supply estimates and viewership-experiment demand estimates. The red bars show two separate counterfactuals. Left of the axis break, they show the shares of lifestyle, stories, and entertainment in consumption if we give lifestyle and stories the supply parameters of entertainment. Right of the axis break, they show the partisan share of political consumption if we give nonpartisan political content the supply parameters of partisan political content, holding all other supply parameters fixed. We consider only user-generated content when analyzing political content, excluding content created by news organizations.

Panel (b) analyzes counterfactuals that account for diminishing marginal utility from content types.

In our lifestyle-focused counterfactual, we assign entertainment's supply-side parameters to lifestyle and stories, hence eliminating lifestyle's supply-side advantage over the other two types. In this counterfactual, the prevalence of lifestyle content in viewers' feeds drops by about a third. The magnitude of the drop is attenuated by diminishing marginal utility, which pushes towards equalization of consumption across types.

In our politics-focused counterfactual, we assign partisan political content's supply-side parameters to nonpartisan content, eliminating partisan content's supply-side advantage. In this counterfactual, the partisanship of consumed political content drops by more than half. The supply side hence appears more important for partisan than lifestyle content. This is because—even though lifestyle faces a demand disadvantage and partisan content a demand advantage—the supply advantage of partisan over nonpartisan content is quantitatively much larger than the advantage of lifestyle over entertainment.

Overall, results suggest the prevalence of both lifestyle and partisan political content is one- to two-thirds supply-driven.

5 Implications: Emotion-Sampling

Section 4 decomposed equilibrium consumption of lifestyle and partisan political content on TikTok into a component driven by supply-side preferences and one driven by demand-side preferences.

A separate issue is whether the demand-side preferences we estimate reflect true viewer preferences or successful exploitation of viewers' self-control problems. For the purpose of our main analysis, this is a secondary question: our model and results are meaningful whether one interprets viewer "utility" as

video brings utility from viewership *and* a fixed cost of exposure to embarrassment.

experienced or decision utility. But it may be interesting to collect some evidence on this question.

In particular, our model in Section 2 suggested that even if viewers dislike some features of a content type, pieces of this type may end up in their feeds thanks to having high residual appeal on *other* dimensions. Appendix J probes this possibility by using emotion data collected via the iPhone app we asked participants to use for a week before sending us their social media histories.

The app detects when a participant is using TikTok, Instagram, or YouTube and pings her at random intervals to ask how she is feeling. This is "experience-sampling," a measurement technique with a history in economics (Kahneman and Krueger, 2006). We link participants' responses to the posts they were viewing at the time the pings were randomly delivered. For identification, we restrict to sessions where a participant is scrolling through an infinite vertical feed and therefore not actively choosing which video will appear next. We implement event study specifications that exploit high-frequency video-to-video variation in the content viewers are served. Such local exogenous variation should exist as long as viewers have a taste for unpredictable moment-to-moment variation conditional on the overall composition of their feeds (Eyal, 2014). We evaluate the exogeneity of the variation by examining pre-trends in our event study plots and implementing balance tests checking whether a viewer's emotions predict the content they are served *next*.

Appendix J describes our methods and reports results. The two content types with the largest negative effects on contemporaneous emotional affect are political content and the subset of lifestyle content that is "enviable," meaning coded as featuring an unusually attractive or wealthy person. This is driven by anger and anxiety in response to political videos and envy or insecurity in response to lifestyle videos.

However, participants seem to like the political and enviable lifestyle videos that appear in their feeds even though they trigger certain negative emotions. Our app occasionally asks participants if they regret watching the video they just watched. Panel (a) of Appendix Figure A66 shows that participants only very rarely report that they regret having watched an enviable lifestyle or partisan political video. After participants submit their viewership histories, we conduct a retrospective survey where we show them a sequence of randomly selected creators from their feeds and ask if they would like the opportunity to block those creators from appearing in their feeds in future. Panel (b) shows that participants say "yes" in a substantial minority of cases but are *less* likely to say yes for enviable lifestyle or political creators compared to random other creators. This is consistent with the possibility that the lifestyle and political creators that do appear in viewers' feeds are sufficiently positively selected on other dimensions to compensate for the negative emotions they trigger.

These results are limited in several respects. They represent only short-run measures of emotions and could not, for example, capture the possibility that repeated exposure to unfavorable social comparisons over a longer period of time could be psychologically deleterious. They capture only emotions, not other outcomes that might matter, like affective polarization or partisan attitudes. And participants may be reluctant to give answers that admit self-control problems. We therefore do not draw firm conclusions and simply note that this pattern of results is consistent with our theory.

6 Conclusion

Two contrasting perspectives marked the early era of social media. An optimistic view saw social media platforms as "liberation technologies" democratizing communication and freeing society from the tyranny of the elites gatekeeping newspapers, radio, and television (Diamond, 2010).

The pessimistic view, which has come to dominate both popular discourse and academic research, sees these platforms as algorithmically tapping into users' personal insecurities and political grievances, driving polarization and social discontent. This view sees the prevalence of politically divisive and "enviable" lifestyle content on social media as a consequence of viewer demand, and attributes the negative effects of social media to platforms' sophistication at identifying and exploiting this demand. From this perspective, the fact that social media enables content creation and distribution by amateurs, whereas legacy media serves content produced by professionals and selected by elite gatekeepers, is largely incidental.

This paper shows that the business model of social media fundamentally derives from a *complementarity* between the production-side differences emphasized by the optimists and the algorithmic sophistication emphasized by the pessimists. By relying on unpaid amateurs rather than paid professionals, platforms amass enormous pools of the types of content that creators are intrinsically motivated to produce. Experimentation and algorithmic personalization then enable platforms to convert the enormous scale of amateur content production into viewer surplus by cherry-picking the videos that will most engage each viewer.

The result has been a fundamental transformation of media consumption in liberal democracies. In the 20th century, people got their political news from professional journalists and entertained themselves by reading or watching books, television shows, or movies produced by writers, directors, and actors paid to cater to their tastes. In the 2020s, they are likely to get their political news from the tiny slice of the population enthusiastic about diving into political arguments online, and their entertainment from the minority of their peers attractive enough to enjoy showing off in front of a camera.

They also spend more time on media consumption than ever before (U.S. Bureau of Labor Statistics, 2026). This is because the turn to amateur production was precipitated by the Internet's facilitation of an enormously successful business model. This paper has characterized this distinctive business model and taken the first step towards tracing out its consequences.

A Additional Figures

Appendix Figure A1: *Production and consumption of content on TikTok, weighting videos by their view counts*

Notes: This figure reproduces Panel (a) of Figure 7, but instead of measuring consumption using our participants' viewership histories, it measures consumption by taking the Research API produced-video sample and weighting each video by its view count.

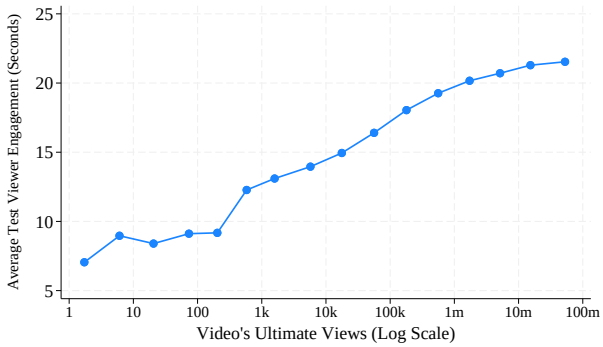

Appendix Figure A2: *Revealing like counts does not increase engagement with highly-liked videos*

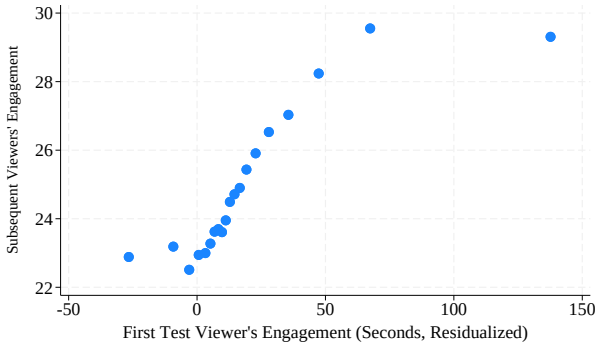

Notes: This figure plots data from our viewership experiment. We randomize at the participant level whether the "like" count on TikTok of the videos they watch is visible or not. The panels show coefficients from regressions of our pre-registered engagement measures on the video's like count separately by whether the count was hidden or not, using our main specification that includes fixed effects for participants, video length decile, and sampling source, the latter interacted with the hidden condition.

Appendix Figure A3: *Identifying tested videos: additional evidence*

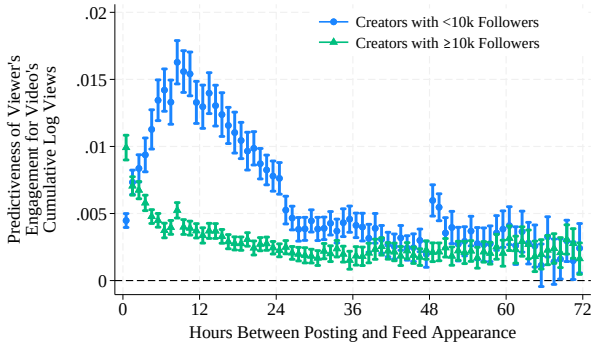

(a) *Test viewers' engagement by the video's eventual views*

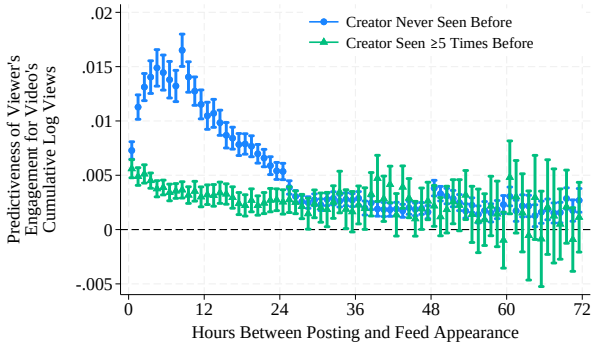

(b) *The first test viewer's engagement and later viewers' engagement*

(c) *Predictiveness of test viewers' engagement for the video's views, by creator size*

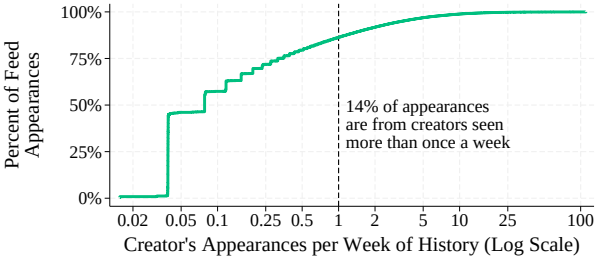

(d) *Predictiveness of test viewers' engagement for the video's views, by creator familiarity*

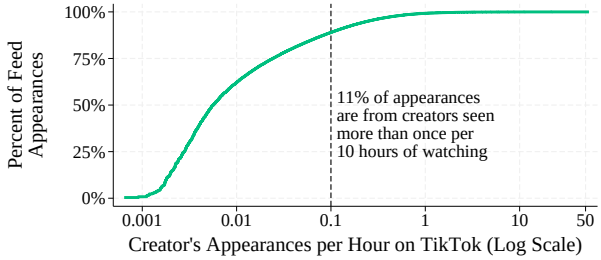

Notes: This figure plots data from our viewership histories, focusing on "test videos" (Figure 4), which are videos that appear in a respondent's feed within 5 hours after being posted. Panel (a) shows that test viewers' average engagement with a video (on the y-axis) is predictive of the video's ultimate views (x-axis) even, for example, above 1 million views. Engagement is measured as seconds watched, controlling for viewer by video duration fixed effects. Panel (b) shows that the engagement of the first test viewer in our data to get a given test video is predictive of the engagement of other viewers in our data who see the same video over the next seven days. Panels (c) and (d) replicate the orange dots from Figure 4 Panel (b) but splitting test videos by whether they come from small or large creators (Panel (c)) and whether they come from a creator who has appeared in the viewer's history before or not (Panel (d)).

Appendix Figure A4: *A small fraction of the typical viewer's feed comes from creators she sees consistently*

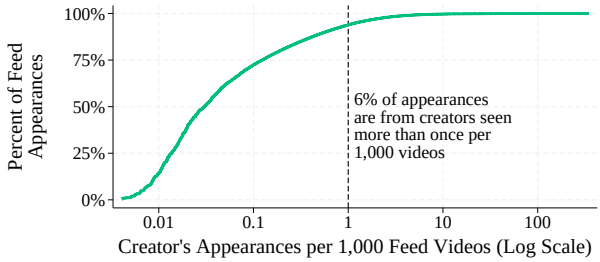

(a) *Consistency measure: creator's average appearances per week*

(b) *Consistency measure: creator's average appearances per hour spent on TikTok*

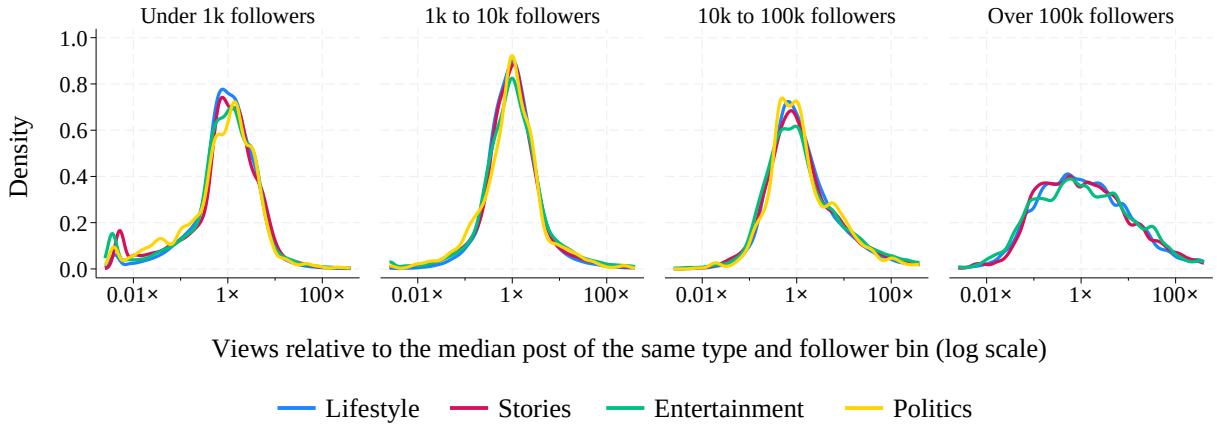

(c) *Consistency measure: creator's average appearances per 1,000 videos watched on TikTok*

Notes: This figure uses data from the viewership histories collected from TikTok users. Each panel plots the cumulative distribution of the videos appearing in viewers' feeds by different measures of how consistently the creator of the video appears in the viewer's feed. Panel (a) uses the creator's number of appearances divided by the viewer's number of weeks observed using TikTok. Panel (b) uses the creator's number of appearances divided by the viewer's total number of hours observed using TikTok. Panel (c) uses the creator's number of appearances divided by the viewer's total number of videos watched. The median history contains 263 hours of usage over 6 months (about 10 hours a week), or about 49,000 videos.

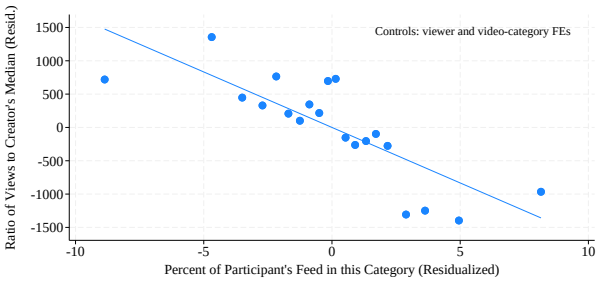

Appendix Figure A6: *The distribution of views has a similar shape for every content type*

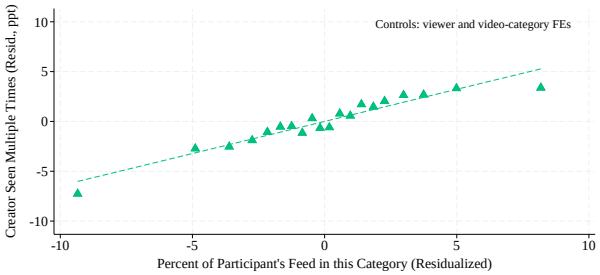

Notes: This figure plots the view count distributions of videos randomly sampled from the pool of all videos produced on TikTok, via the Research API. We plot distributions separately for our four broad content types and by bins of creator follower counts. We center distributions at the type-by-follower bin's median viewership.

Appendix Figure A5: *Preference dispersion → pass-through of all content types to consumption*

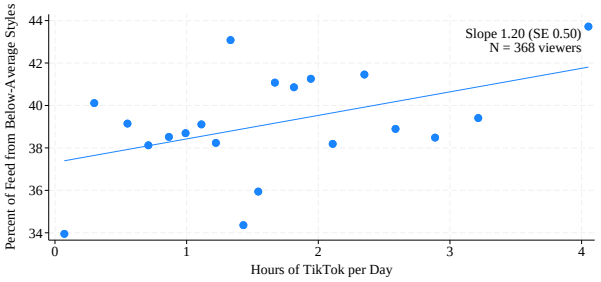

(a) Pass-through: *Videos from categories a viewer doesn't usually see are larger outliers*

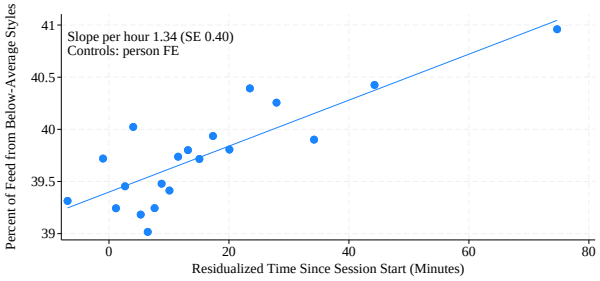

(b) Pass-through: *... and come from creators the viewer rarely sees again*

(c) Scarcity: *Heavier users get more of their feed from styles they see less than the average viewer...*

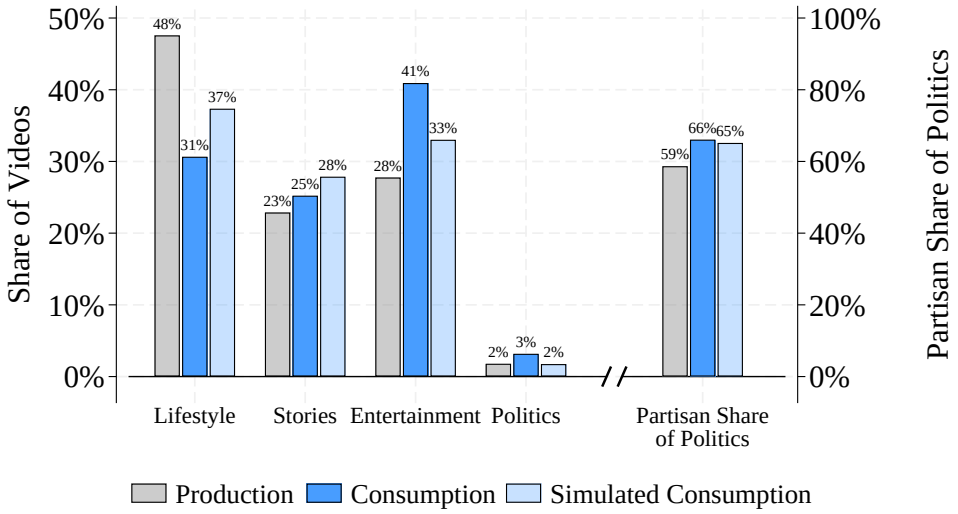

(d) Scarcity: *... and so do viewers further into a session*

Notes: This figure uses data from our TikTok viewership histories and uses our schema categorizing videos into 17 categories described in Appendix C. The x-axes in Panels (a) and (b) plot the percent of a participant's feed in a given category, residualized on participant and category fixed effects, so values above zero indicate categories the participant sees more frequently than other participants. The y-axes plot the dispersion measures from Panels (c) and (d) of Figure 4: the ratio of the view count of a video appearing in the participant's feed to the creator's median view count on their videos, and whether this creator is observed in this participant's feed more than once. The y-axes on Panels (c) and (d) plot the percent of videos a participant sees from categories they see less often than average. Both x-axes plot proxies for content scarcity. The x-axis in Panel (c) plots the participant's average daily hours spent on TikTok based on their viewership history. The x-axis in Panel (d) is the same as in Panel (b) of Figure 6: how far into a given TikTok session a participant is.

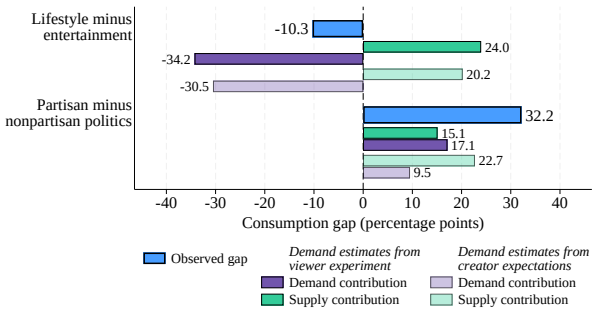

Appendix Figure A7: *Production, consumption, and simulated consumption of content types, using demand estimates from creators' expectations*

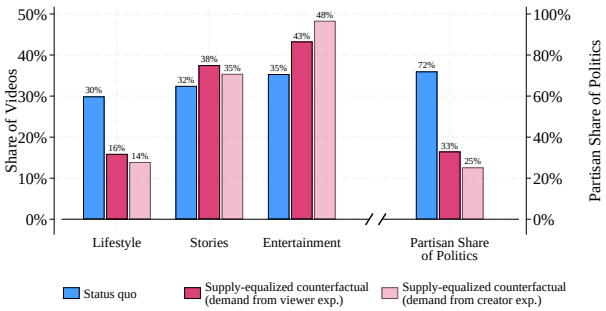

Notes: This figure replicates Figure 11 Panel (d) but simulates consumption using demand estimates sourced from the expectations of creators in our creator experiment, rather than from our viewership experiment.

Appendix Figure A8: *Oaxaca decomposition of observed consumption gaps, and counterfactual consumption rates after equalizing supply parameters, allowing the value of views β to vary by content type*

(a) *Decomposition of consumption gaps into supply and demand*

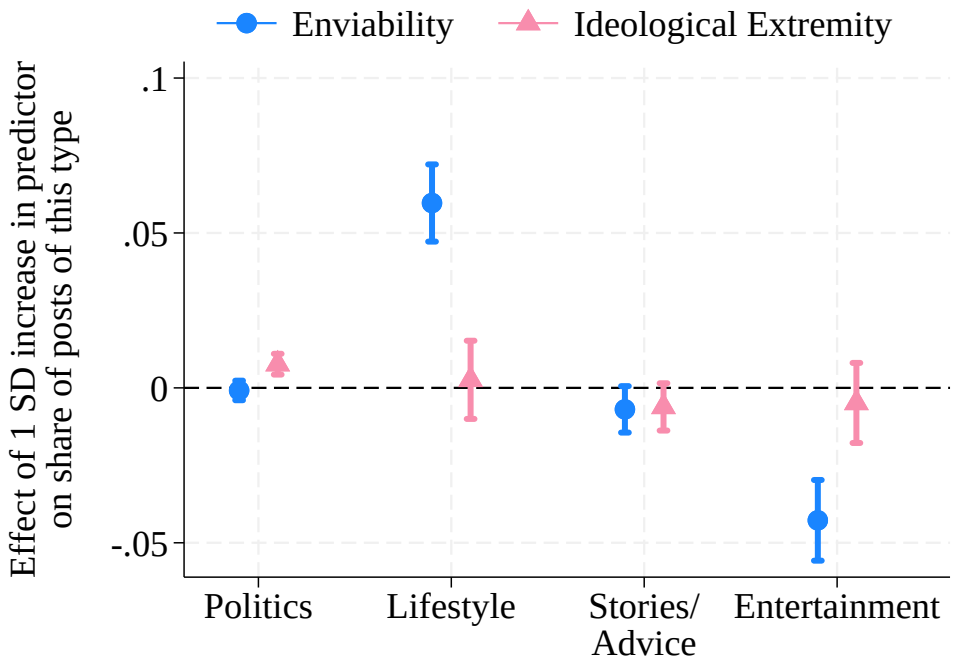

(b) *Consumption with supply-side parameters equalized*

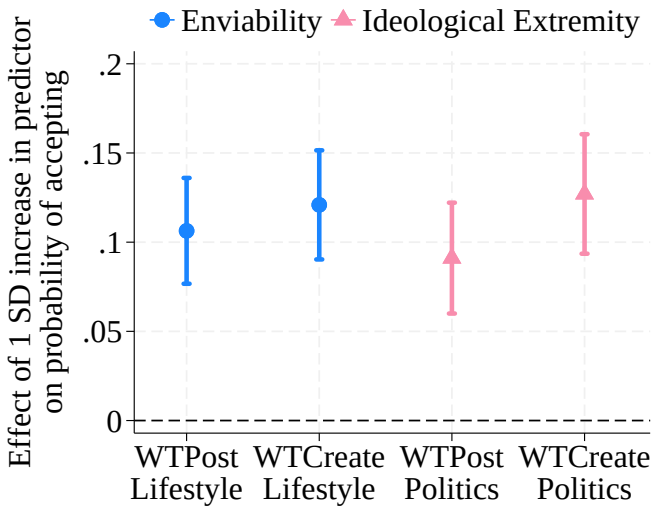

Notes: This figure replicates Figure 13 but using model estimates that allow β to differ by content type.

Appendix Figure A9: *Enviability, ideological extremity, and the share of posts of each content type*

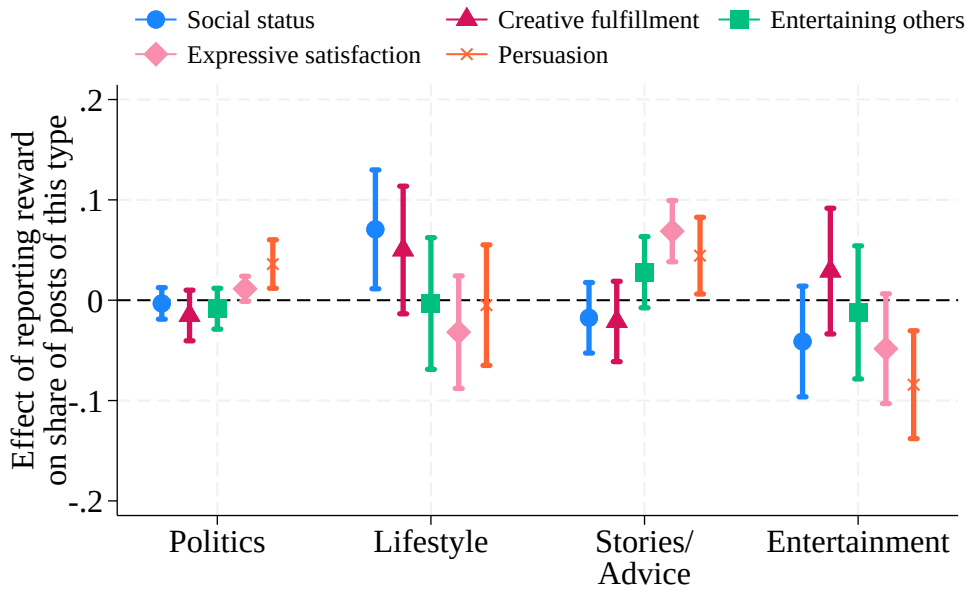

Notes: This figure reproduces Figure 8 Panel (b), but the outcome is the share of a user's scraped posts falling into each content type rather than an indicator for having posted that type. We scrape every TikTok post users made from April to June 2026 through the Research API, users' recent posts on X/Twitter, and users' 12 most recent posts plus up to 30 Reels on Instagram. Each coefficient is from a regression of the share on enviability and ideological extremity (both standardized) with platform fixed effects, with one observation per user and platform.

Appendix Figure A10: *Enviability and extremity equally predict willingness to* ***post*** *and to* ***create***

Notes: This figure uses data from our survey of users of our four platforms of interest, with enviability and ideological extremity measured as in Figure 8. It plots responses to questions offering respondents $3 to either post (for 50% of respondents) or privately create (other 50%) different types of content. It correlates willingness to post/create lifestyle content with enviability and political content with extremity, controlling for average willingness to produce other types.

Appendix Figure A11: *Creators who say they get different rewards from creating post different types of content*

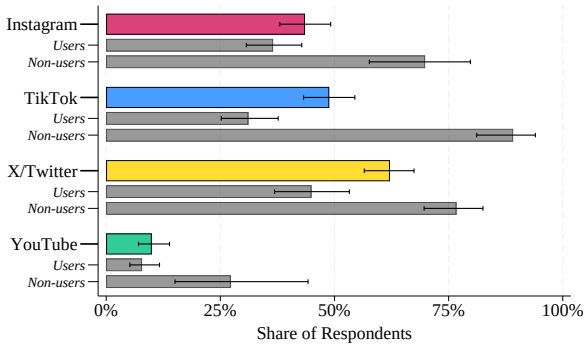

Notes: This figure uses data from our creator survey. It plots coefficients from regressions of the shares of a creator's posts (which we scrape from their account and classify) falling into each of our content quadrants on indicators for whether the creator reported receiving a specific nonpecuniary reward from content production.

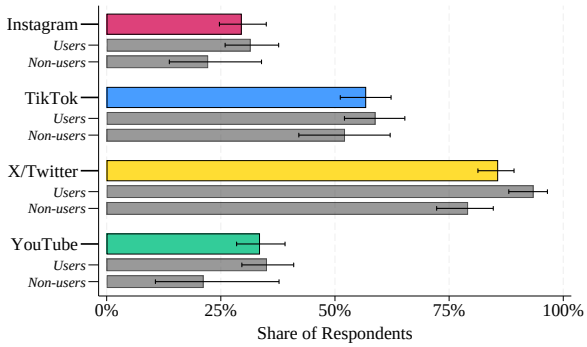

B Results for Instagram, X/Twitter, and YouTube

Appendix Figure A12: *Attitudes towards Instagram, TikTok, X/Twitter, and YouTube*

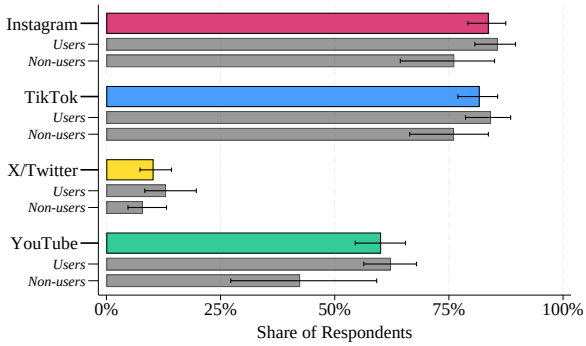

(a) *Wish it didn't exist*

(b) *Associate with politics*

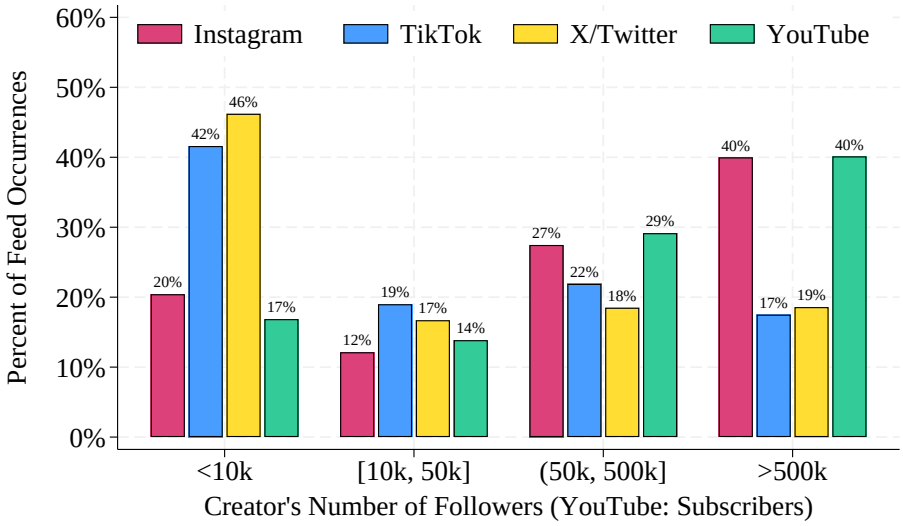

(c) *Associate with lifestyle*

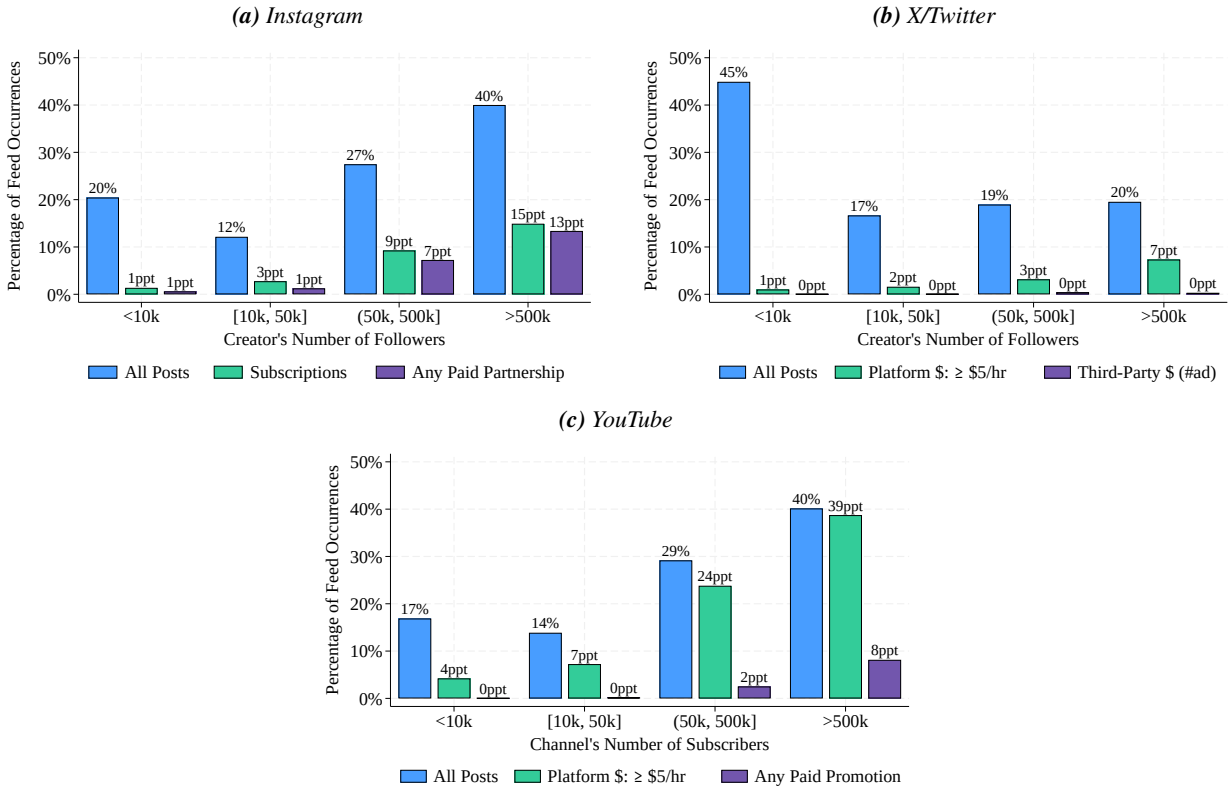

Notes: This figure shows responses from a survey of 301 Americans aged 18–30 recruited on Prolific. Panel (a) plots the share of respondents who say "yes" to "Would you prefer to live in a world where [platform] did not exist," separately for each of Instagram, TikTok, X/Twitter, and YouTube, and separately by respondents who report using versus not using the relevant platform. Panels (b) and (c) plot the share of respondents who say they associate this platform with "having a lot of content about politics and political opinions" and "having a lot of lifestyle content, meaning content focused on appearance, fashion, fitness, wealth, and so on," respectively.

Appendix Figure A13: *Distribution of posts in viewers' feeds across account sizes, by platform*

Notes: This figure replicates Figure 4 Panel (a) for each of our four platforms of interest. Private Instagram accounts whose follower counts cannot be scraped are allocated to the $< 10k$ bucket.

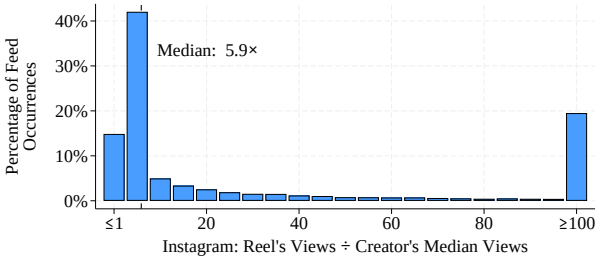

Appendix Figure A14: *What fraction of posts in viewers' feeds earn money for their creators? Instagram, X/Twitter, and YouTube*

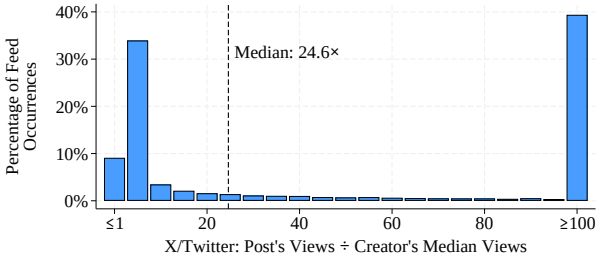

Notes: This figure reproduces Figure A29, asking what percentage of posts viewers see on each platform come from creators who appear to ever earn money on those platforms. Instagram has no program analogous to Creator Rewards. We therefore plot the percentage of creators offering paid subscriptions via their profile ("Subscriptions") and the percentage of creators with any Reel tagged as a paid partnership ("Paid Partnership") over the 7 months covered by our data. X/Twitter has a revenue sharing program, so the green bars plot the percentage of creators estimated to make at least $5/hour assuming the commonly reported payout rate of $8.50/million views and assuming a text-based post takes 6 minutes, a photo-based post takes 15, and a video 30. The purple bars plot the share of creators who have any posts with a #ad, #sponsored, or other similar tag suggesting third-party money. YouTube also has a revenue sharing program for channels with at least 1,000 subscribers. The green bars assume $2 per 1,000 views for main videos and $0.05 for Shorts based on common estimates, and assume conservatively that a Short takes 30 minutes and a long video takes 2 hours to produce. The purple bars use YouTube's paid-promotion tags.

Appendix Figure A15: *Dispersion on Instagram, X/Twitter, and YouTube*

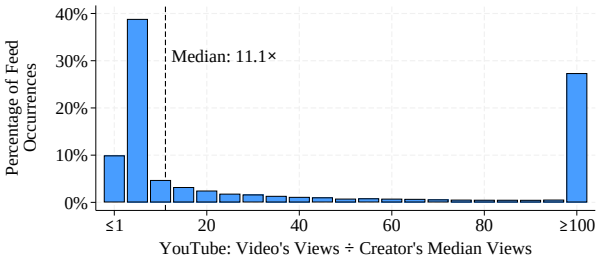

(a) *Instagram: Reels' views relative to their creator's median views*

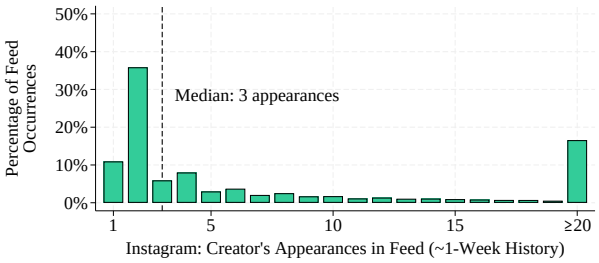

(b) *X/Twitter: posts' views relative to their creator's median views*

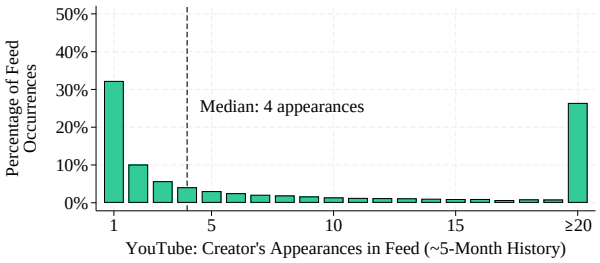

(c) *YouTube: videos' views relative to their channel's median views*

(d) *Instagram: how many times viewers see each creator*

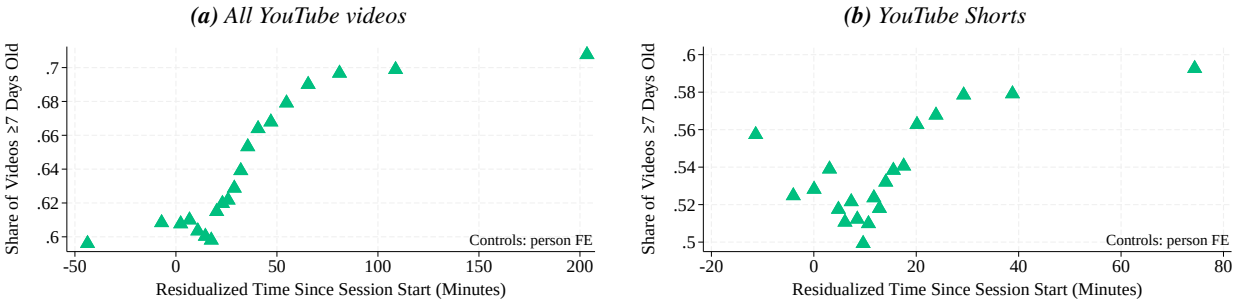

(e) *YouTube: how many times viewers see each channel*

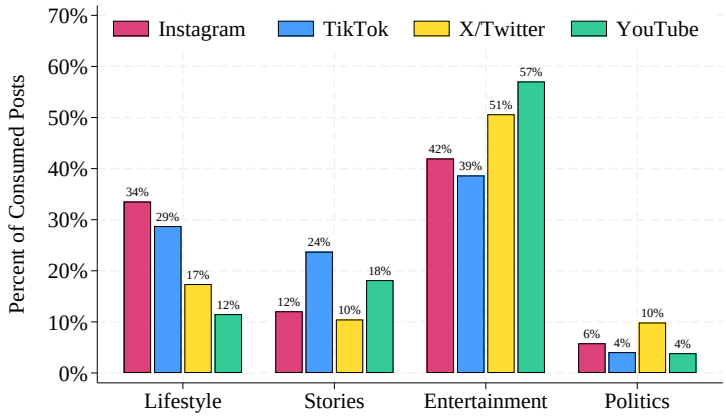

Notes: This figure reproduces Panels (c) and (d) of Figure 4 for our other platforms. Panels (a)-(c) plot the ratio of a consumed video's view count to its creator's median view count across their other videos. For YouTube and X/Twitter, this is straightforward. For Instagram, we do not see which specific post from a creator appeared in a person's feed, so instead we sample recent Reels by this creator, weight them in proportion to their views, and divide by the creator's median Reels views. Panels (d) and (e) plot the number of times a creator appears. This is not possible on X/Twitter because our scraped data for a participant's feed only contains 300 recent posts, not enough to observe repeated appearances by creators over any meaningful time period.

Appendix Figure A16: *Scarcity on YouTube: stale videos within sessions*

Notes: This figure reproduces Figure 6 Panel (b) for YouTube. Panel (a) includes all YouTube videos and Panel (b) includes YouTube Shorts. This is not possible for Instagram because we observe only the creators appearing in a viewer's feed and not which specific posts appear, and not possible on X/Twitter because we only observe an automated scroll of the first 300 posts in a feed.

Appendix Figure A17: *Content consumed on Instagram, TikTok, X/Twitter, and YouTube*

Notes: This figure reproduces Figure 7 Panel (a) for our other three platforms. All four platforms are classified using `GPT-5-mini` and the same classification prompt. For Instagram, we see which creators appear in a participant's feed but not which specific posts, so we scrape creators' recent posts, classify them, and weight by their view counts. For YouTube, we exclude videos classified as music videos (which are presumably listened to but not watched).

C Observational Data and Classification

Recruitment for viewership histories, user survey, and experiments. Participants in our surveys and experiments are 18-30 year old Americans predominantly recruited from Prolific (with a few recruited from the survey platform MobLab). Tables A1–A4 compare them to nationally representative samples of users of the same platforms. Relative to the general youth population, users of our platforms, especially TikTok, skew more female, left-wing, and ideologically extreme. Our samples skew even further in these directions as well as being more educated.

Data for our viewership history collection and emotion sampling were collected between October 2025 and January 2026 and our hypotheses and empirical strategy for estimating the effects of social media content on emotions were pre-registered on the Open Science Framework at `https://osf.io/8ctq7`. We screened 6,529 Prolific users for eligibility (asking about their social media usage) and invited 2,513 to an onboarding

survey. 673 register for our emotion-sampling iPhone app and 383 complete a week of using the app and submit their viewership histories. Table A5 traces out sample characteristics at each step of this process.

Data for our user survey were collected between June and July 2026. Users were required to log in with either a TikTok or X/Twitter account to access the survey and were paid bonuses for also logging in with the other account and/or giving us their Instagram handle (since we could not build a login tool for Instagram). Our YouTube login tool was not approved at the time so we retrospectively re-survey participants in our user survey to get them to log in with YouTube in September 2026.

Social media histories. We collect social media histories for Instagram, TikTok, and YouTube.

The common features of these histories are as follows: each contains a chronological list of the posts a user has seen on the platform, with the post's URL (TikTok and YouTube) or just the username of the account that made the post (Instagram), and with a timestamp indicating when the user swiped into or clicked onto this post. These records include ads the user sees as they swipe or watch. For Instagram and YouTube these ads are in a separately labelled file, whereas for TikTok they appear as URLs and we scrape metadata indicating whether a video is an ad. We use the URLs to scrape video metadata, including duration, view and like counts, transcripts, captions, thumbnails, top comments, commercial metadata (ad and sponsorship tags), and details about the creator such as their follower count, posting volume, bio, and so on.

We use the timestamps to infer how long a user spends on a particular post. For example, if a user swipes into a 65-second video and then swipes into another video 18 seconds later, we infer that they watched the first video for 18 seconds. We cap this at the length of the video (65 seconds). We also use the timestamps to separate out contiguous "sessions" of usage; a session ends at a video where the next video begins at least 5 minutes later (TikTok, Instagram, YouTube Shorts) or at least 30 minutes later (YouTube). The last video in a session is not assigned a watch time. Table A6 shows descriptive statistics about videos and sessions.

Where these histories differ is on the following points. The Instagram histories reach back 7 days, the TikTok histories 6 months, and the YouTube histories back to the creation of an account. The Instagram histories also only allow us to observe which account made the post seen by the user, not the URL of the specific post itself. For this reason, our descriptive results using Instagram scrape a sample of recent posts for these accounts and take a view-weighted average across them.

C.1 Descriptive statistics on samples

Appendix Table A1: *Our samples of TikTok users compared to nationally representative surveys*

	Our samples			Pew ATP 2023-25		ANES 2024		YouGov 2025

Content Creation			
Has Posted on TikTok	0.62 (0.48)	0.99 (0.09)	1.00 (0.03)
TikTok Followers, Median [p10, p90]	82 [10, 1,308]	4,119 [288, 217,700]	20,200 [638, 1,300,000]
TikTok Posts, Median [p10, p90]	3 [0, 103]	224 [20, 1,429]	445 [33, 2,525]
Observations	3,490	923	752

Note: This table shows descriptive statistics for participants in our user survey and creator survey. For the latter, we show statistics separately when weighting all respondents equally versus when using TikTok respondents and weighting them to match the distribution of follower counts in the TikTok histories of our participants. Follower and post counts are scraped directly from their accounts; all other outcomes are survey outcomes.

C.2 Content classification

We classify posts and videos using `GPT-5-mini`. For TikTok videos, we give the model the video's transcript, caption, creator's name and bio, text that appears on-screen, and the video's thumbnail image. For Instagram posts or Reels, we give the model the post's caption, hashtags, creator username and bio, location and music tags, and an image (either the video's thumbnail or the first image in an image post). For YouTube videos, we give the model the video's title, description, transcript, and category, the channel's name, and a thumbnail image.

The model assigns each video one category out of the seventeen mutually exclusive lower-level categories displayed in Table A8. The bold lines are then our aggregation of those classifications into higher-level categories. In addition to assigning a category, the model classifies whether a video is "enviable" (meaning prominently featuring an unusually attractive or wealthy non-celebrity) and tags any news topics the video discusses. A follow-up classification step applied to political videos classifies whether the video expresses a clear partisan perspective.

Appendix Table A8: *Content types and the style categories they contain*

Content type and style category	Share of videos (%)
Lifestyle	**28.7**
Appearance	15.5
Wealth	1.2
Day in the life	3.6
Music, dance, or performance	6.2
Travel or outdoors	2.3
Stories, gossip, and advice	**23.7**
Advice or product recommendation	10.3
Storytime or gossip	13.4
Entertainment	**38.6**
Meme, joke, or comedy sketch	14.0
Video gaming	1.8
Pop culture, movies, or film	6.7
Sports	2.3
Food or cooking	5.5
Pets or animals	4.3
DIY, crafts, or art	2.2
Tech, science, or education	2.0
Politics	**4.1**
Political news or discussion	3.4
Other styles flagged as political	0.7
Not assigned to a content type	**4.8**
Other	4.8
Videos	498,890

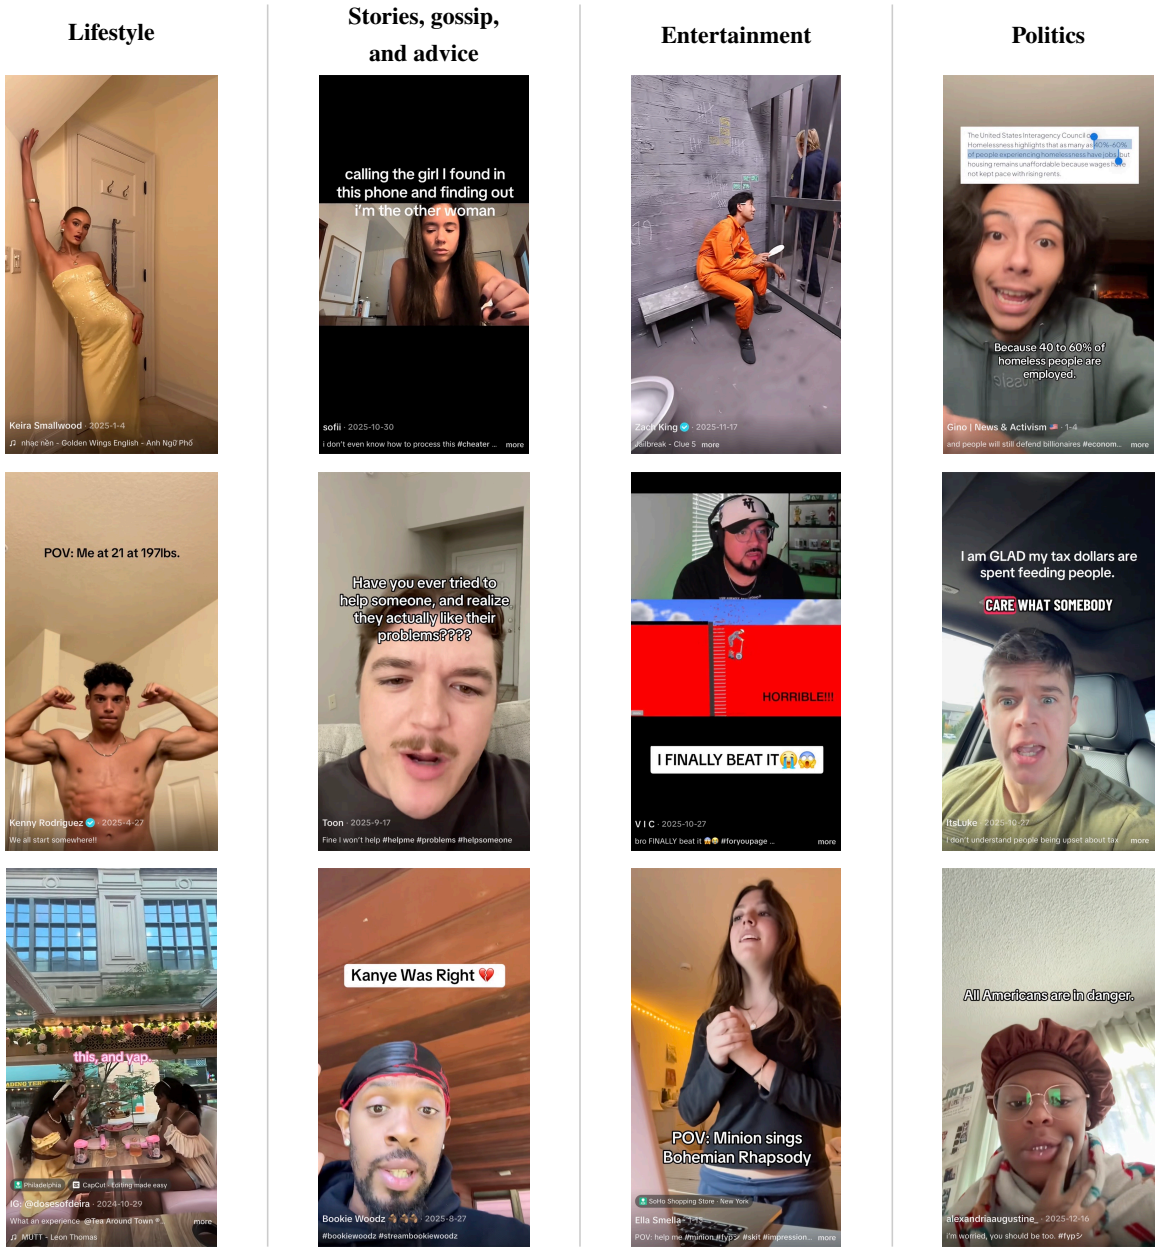

Notes: This table lists our four broad content types and the underlying specific content types from our schema that are aggregated into these broad types. Our LLM classification assigns each video the one specific content type that best fits it. The percentages show the shares of each content type in participants' viewership histories.

Appendix Table A9: *Agreement between human coders and the LLM classifier*

	Videos	Human vs. LLM	Human vs. human
Panel A: All test videos			
Broad content type agreement	992	53%	52%
Broad content type κ	992	0.39	0.37
Specific content type agreement	992	42%	40%
Panel B: Agreement by the LLM's broad and specific content type			
Lifestyle	**240**	**56%**	**53%**
Appearance	79	41%	34%
Wealth	34	43%	34%
Day in the life	41	48%	34%
Music, dance, or performance	49	11%	31%
Travel or outdoors	37	56%	44%
Stories, gossip, and advice	**236**	**34%**	**43%**
Advice or product recommendation	101	31%	31%
Storytime or gossip	135	27%	33%
Entertainment	**240**	**67%**	**56%**
Meme, joke, or comedy sketch	30	41%	38%
Video gaming	30	73%	67%
Pop culture, movies, or film	30	48%	29%
Sports	30	64%	58%
Food or cooking	30	56%	45%
Pets or animals	30	35%	28%
DIY, crafts, or art	30	51%	40%
Tech, science, or education	30	31%	32%
Politics	**237**	**60%**	**54%**
Political news or discussion	196	64%	56%
Other styles flagged as political	41	41%	47%
Not assigned to a content type	**39**	**15%**	**59%**
Other	39	15%	59%

Notes: This table shows agreement rates between our LLM and Prolific-recruited human handcoders. The "human vs LLM" column shows the percentage of the time (across videos) that a human's pick matches the LLM's pick, while "human vs human" is the equivalent for two humans coding the same video. κ is Cohen's kappa.

Appendix Figure A18: *Examples of TikTok content types*

These next figures report results of a sparse auto-encoder applied to (i) our viewership experiment data, (ii) our production-vs-consumption observational data (Figure 7), and (iii) our discontinuities-at-60-seconds data (Figure 9).

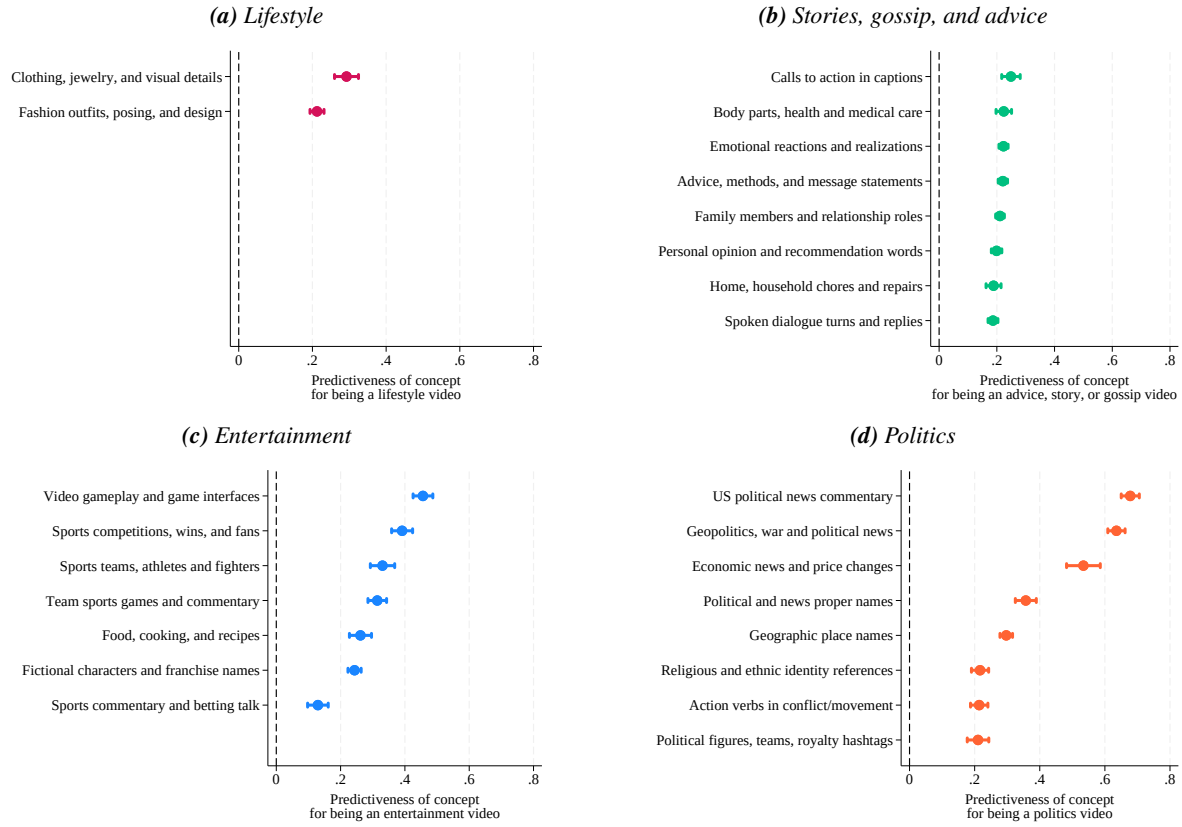

We prepare the underlying data by taking each video's caption, on-screen text, and transcript and adding a description of its imagery obtained by having `GPT-5-mini` describe four frames from the video (experimental videos, for which we have MP4s) or the thumbnail of the video (observational videos). We use the Gemma Scope sparse auto-encoder on the Gemma-2-2B language model to break videos into concepts.

For the experimental data, we regress engagement (residualized on the fixed effects from our main specifications) on each concept and keep those that predict engagement after the multiple-testing correction

of Carlson (2026). We use Claude Opus 5.5 to label concepts based on the videos they appear in and group concepts into themes. We then check which concepts are predictive of which content types.

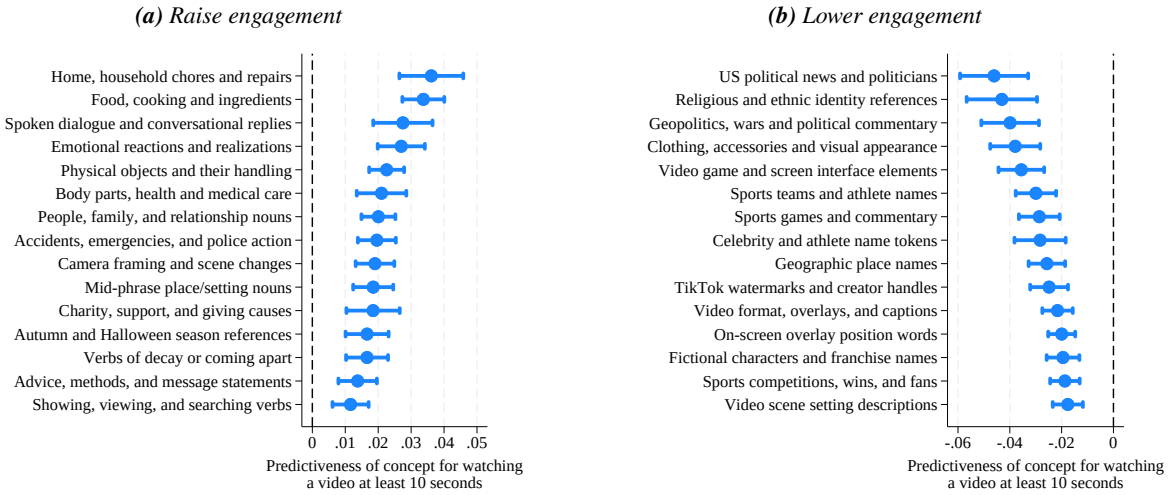

For the observational data, we predict whether a video is consumed versus produced or whether a video is just over versus just under 60 seconds long, and then follow a similar procedure.

Appendix Figure A19: *Concepts most predictive of each content type*

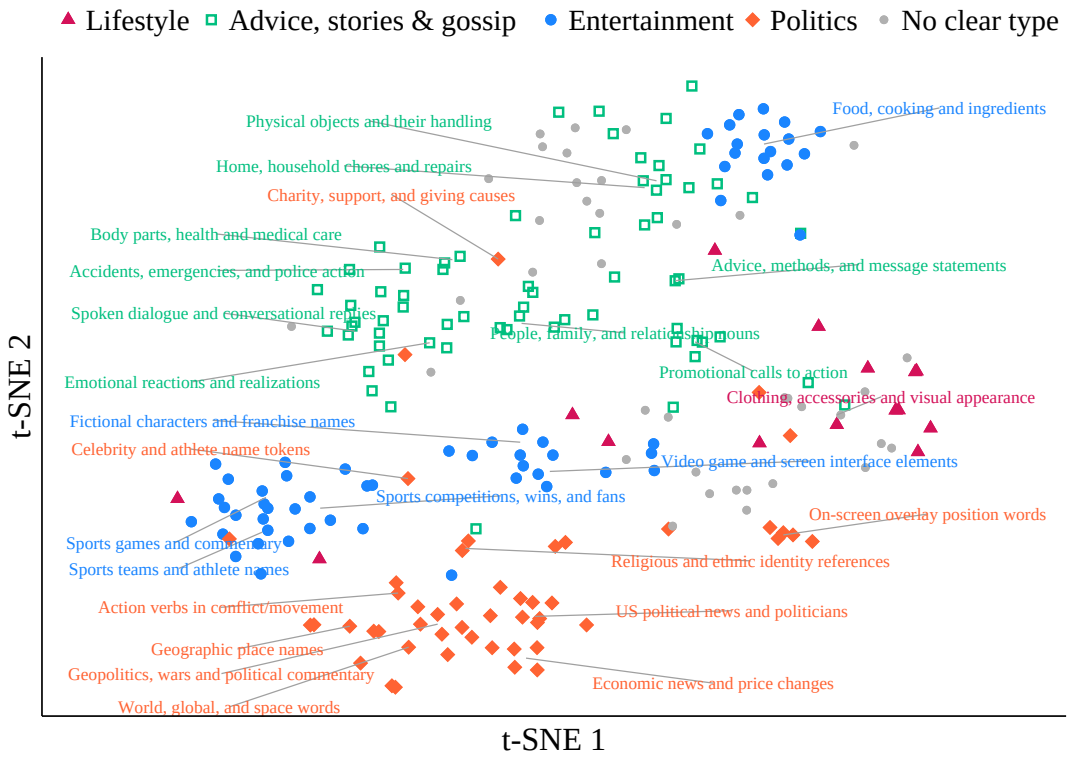

Notes: This figure shows, for each of our four content types, the concepts discovered by the sparse auto-encoder whose presence in a video most strongly predicts this content type. The sample consists of videos from our viewership experiment and we retain concepts that predict engagement at the 5% level after the multiple testing correction of Carlson (2026) and that appear in at least 2% and under 50% of videos. Claude groups concepts into themes and the coefficients here show themes, with the label of a theme being the concept in the theme that is most predictive of the relevant content type.

Appendix Figure A20: *Concepts most predictive of engagement*

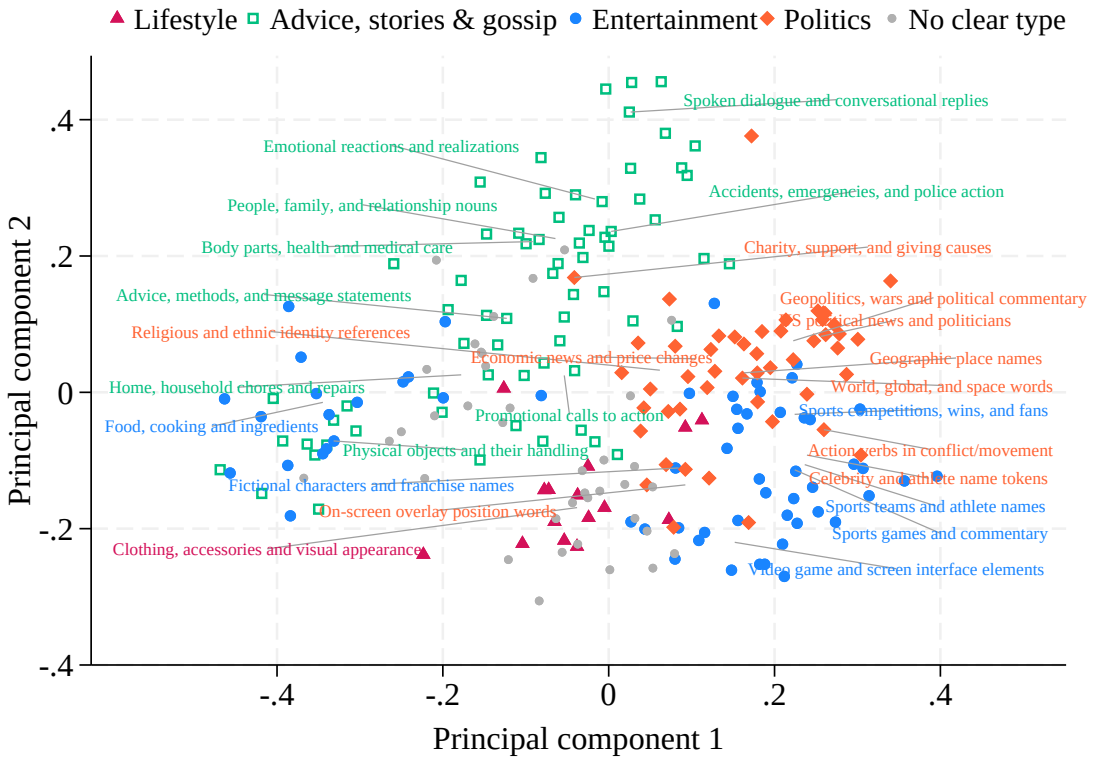

Notes: This figure shows the concepts discovered by the sparse auto-encoder that are most predictive of engagement (specifically, those with the largest positive and largest negative t-statistics). The x-axis shows coefficients from regressions of experimental engagement (the share of viewers seeing a video who watched it for at least 10 seconds) on an indicator for the relevant concept being present in the video, using our main engagement specification.

Appendix Figure A21: *Clustering of discovered concepts*

Notes: This figure shows clustering of the concepts from Figure A19 in a t-SNE plot (van der Maaten and Hinton, 2008), which positions concepts so that concepts that tend to appear in the same videos are placed near each other. The cardinal distance between clusters is not meaningful and the axes have no units or interpretation.

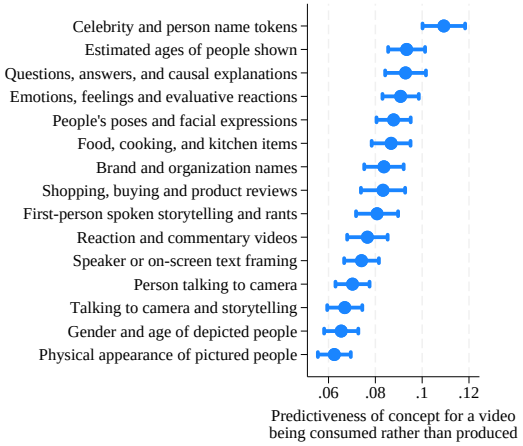

Appendix Figure A22: *Clustering of discovered concepts: principal components*

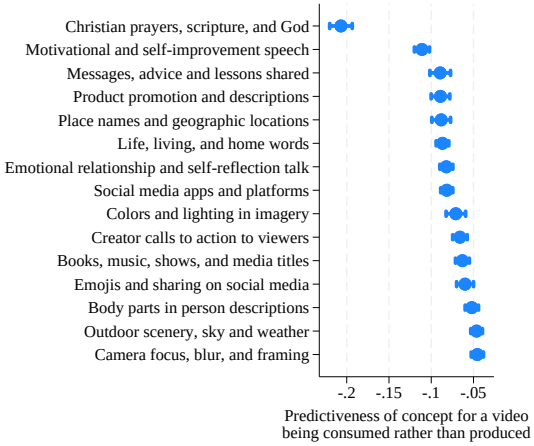

Notes: This figure replicates Figure A21 using principal components as the axes. They are the first two principal components of a matrix where a row is a concept, a column is a video, and the entries record whether the concept appears in the video. That is, they capture the two principal components of the pattern of concepts' appearances in videos.

Appendix Figure A23: *Concepts most predictive of a video being consumed rather than produced*

(a) *More common in consumption*

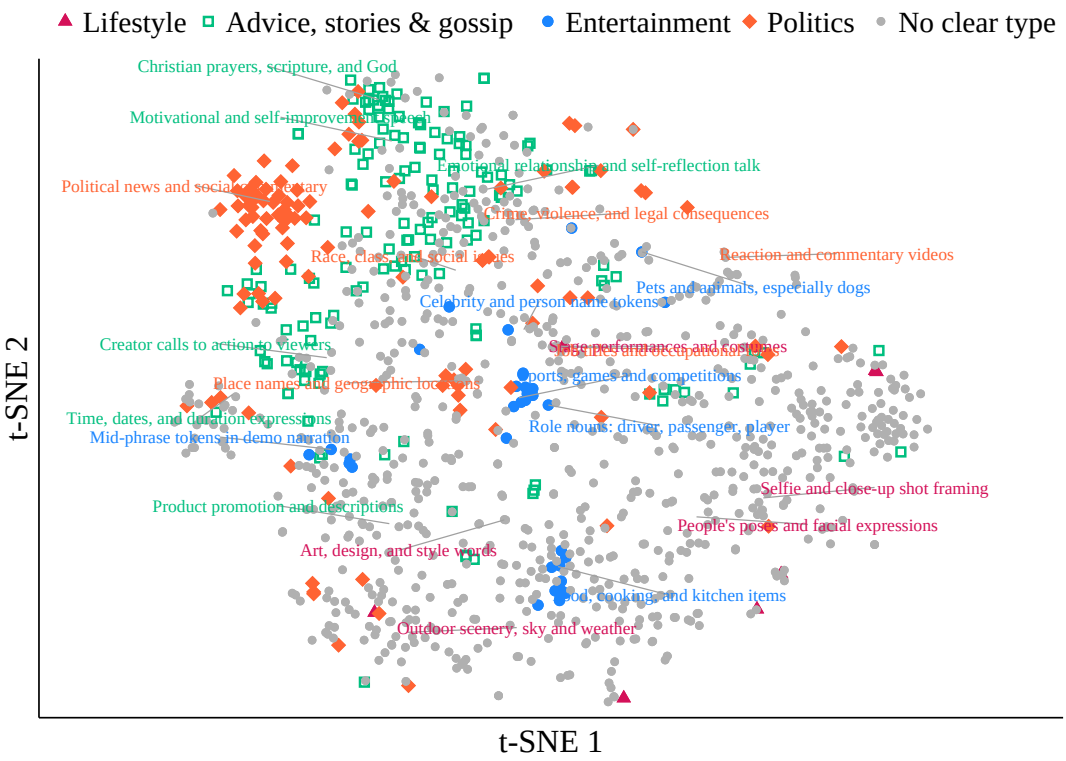

(b) *More common in production*

Notes: This figure is analogous to Figure A20, but uses results from a sparse auto-encoder applied to our observational consumption vs. production data and shows which concepts are most predictive of whether a video appears in the "consumed" set as opposed to the "produced" set.

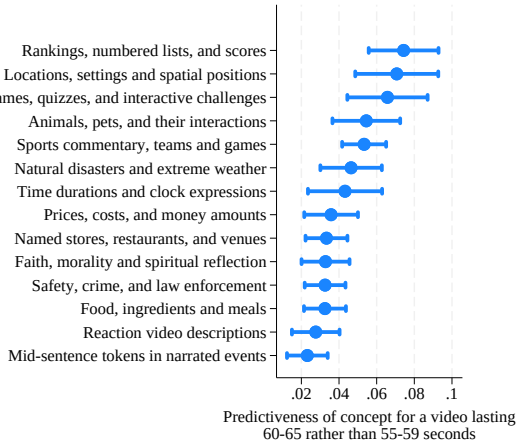

Appendix Figure A24: *Clustering of concepts predicting consumption rather than production*

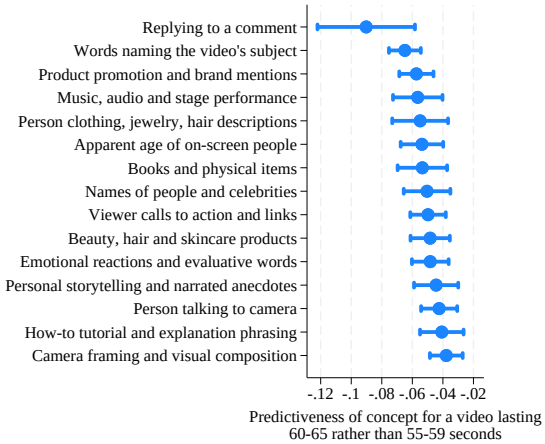

Notes: This figure replicates Figure A21, but uses results from our sparse auto-encoder applied to our observational "produced versus consumed videos" data.

Appendix Figure A25: *Concepts most predictive of a video lasting just over rather than just under 60 seconds*

(a) *More common at 60-65 seconds*

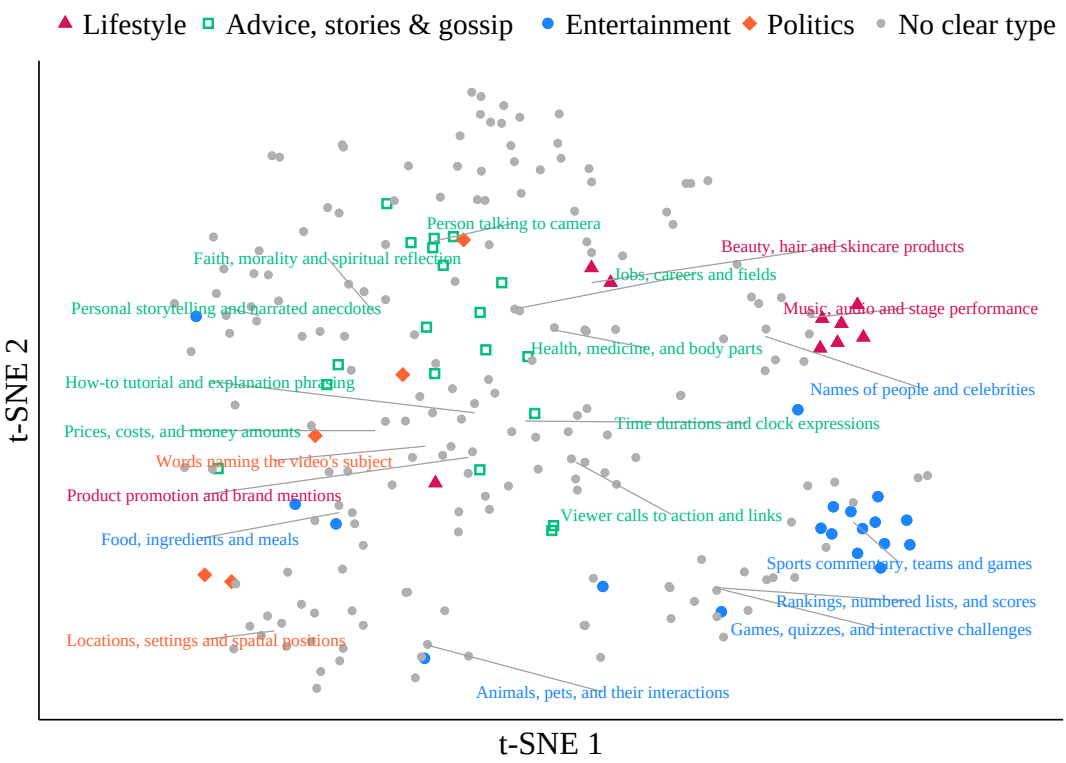

(b) *More common at 55-59 seconds*

Notes: This figure is analogous to Figure A20, but uses results from a sparse auto-encoder applied to our observational video-duration data and shows which concepts are most predictive of whether a video is just under or just over 60 seconds long.

Appendix Figure A26: *Clustering of concepts predicting video length around 60 seconds*

Notes: This figure replicates Figure A24, but uses concepts from Figure A25.

D Identifying Algorithmic Markups

This section tests for algorithmic markups following the ideas of Kleinberg et al. (2018) and Rambachan (2024). We take the pool of videos in our participants' TikTok viewership histories, encompassing 20.6 million total video appearances, and train a prediction model. The inputs are video metadata (length, age when shown, time of day, position in scrolling session, whether it is an ad, caption, transcript, on-screen text, creator username) and viewer information (aggregate engagement rate, earlier engagement with same creator, similarity of video's text embeddings to earlier videos in the session, viewer-by-content interactions). The model predicts for how many seconds a viewer watches a video. We generate embeddings using `gte-multilingual-base` fine-tuned using contrastive learning on 20,000 TikToks. The model achieves an out-of-sample R^2 of 0.187 for "number of seconds watched" and 0.406 for "share of a video watched."

We train the model on an 80% sample and hold out 20% of the sample for evaluation. In the figure below, we split videos from the evaluation set falling into different categories by ventiles of predicted engagement according to the model and plot their actual engagement on the y-axis.

The intuition is that if the platform does not apply algorithmic markups—it equates engagement with the marginal video of each type—the lines should intersect at the bottom ventile. If one line remains persistently elevated above the other, this indicates the line below it is algorithmically subsidized—the platform serves

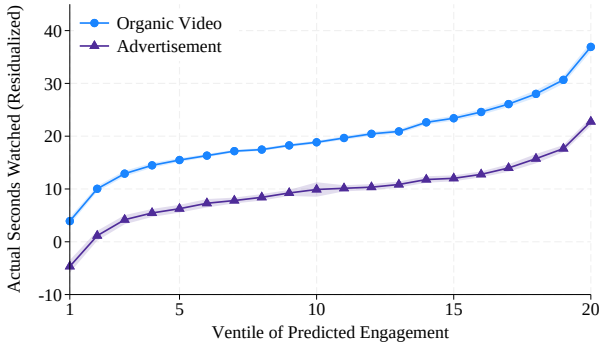

videos of that type even when the marginal video it serves will predictably receive lower engagement than the marginal video of another type.

Panel (a) shows that advertisements are algorithmically subsidized relative to organic videos according to this measure, which makes sense as advertisements definitionally are videos a creator or sponsor has paid to subsidize algorithmically. Panel (b) shows that non-advertisement videos with third-party sponsorship tags are also subsidized algorithmically. 80% of these are videos with TikTok Shop affiliate links; TikTok takes a direct cut on these sales, so it makes sense for those videos to be algorithmically subsidized. Figure A28 shows that it is indeed TikTok Shop videos that drive this subsidization, and videos sponsored by third parties that do *not* link to the TikTok Shop are not subsidized at all.

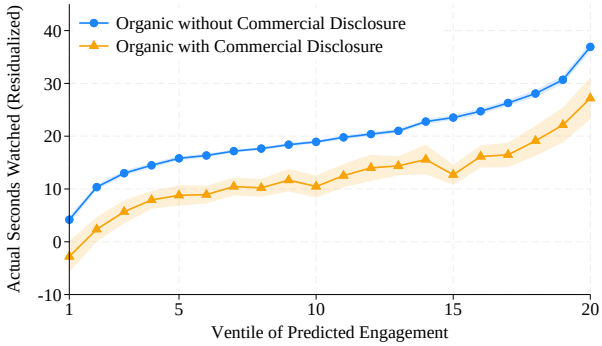

Panels (c) and (d) show that, by contrast, none of the content types we are interested in appear to be algorithmically subsidized relative to the others: the bottom ventiles' confidence intervals all cross.

Appendix Figure A27: *Testing for algorithmic markups: actual versus predicted engagement*

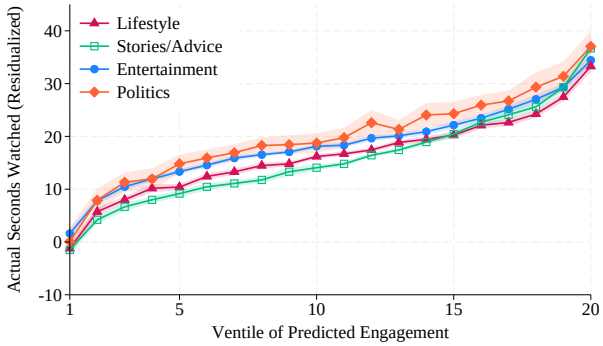

(a) *Advertisements versus organic videos*

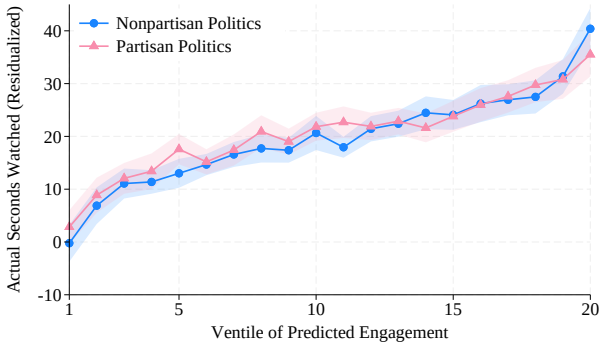

(b) *Organic videos with and without a commercial disclosure*

(c) *Content types*

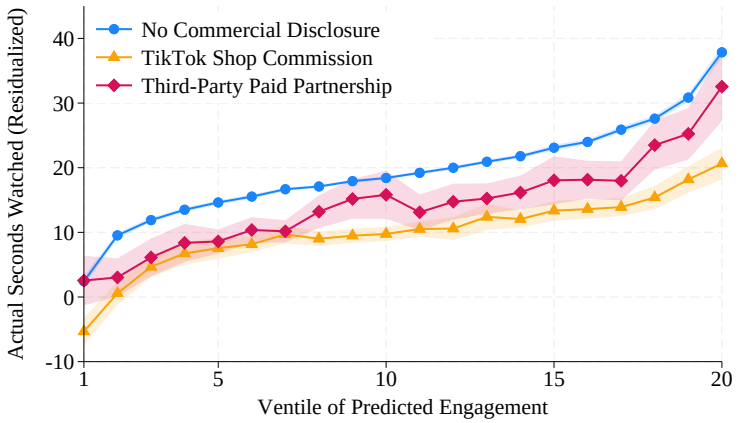

(d) *Partisan versus nonpartisan political content*

Notes: This figure plots data from our participants' viewership histories. In each panel, the x-axis plots ventiles of predicted engagement. The y-axis plots actual engagement by viewers with videos in this ventile, residualized on participant-by-video-length fixed effects. Shaded bands are 95% confidence intervals clustered by participant.

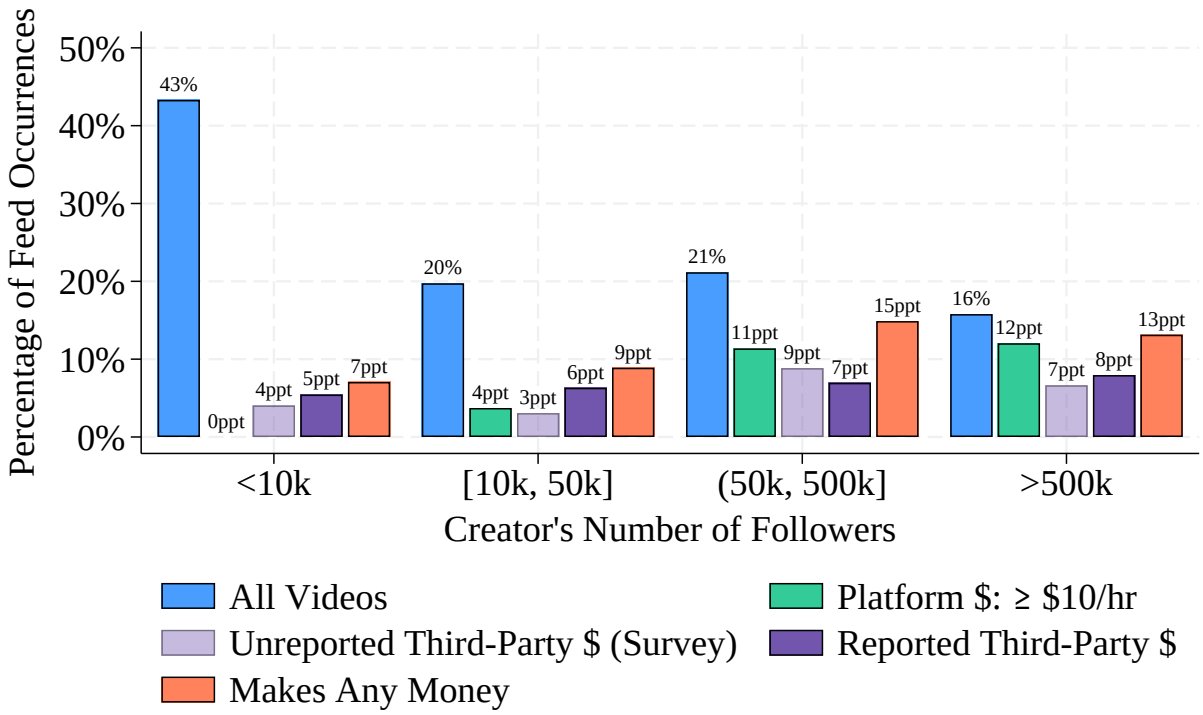

Appendix Figure A28: *Testing for algorithmic markups: TikTok Shop versus third-party sponsored videos*

Notes: This figure replicates Panel (b) of Figure A27 but splits videos with commercial disclosures by whether the disclosure is a link to a TikTok Shop product or a different kind of third-party sponsorship.

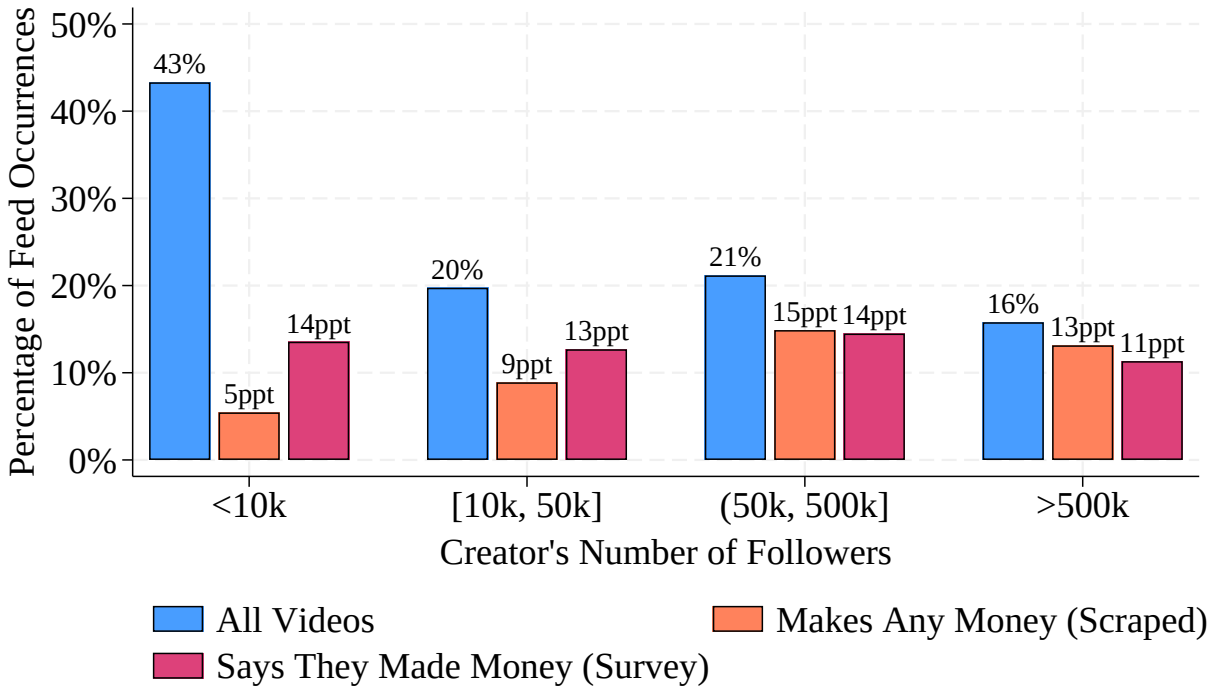

E Creator Survey, Monetization, and Motivations

Appendix Figure A29: *What fraction of the videos viewers see come from creators who ever earn money?*

Note: This figure replicates Figure 5 Panel (a), except the green and purple bars—instead of plotting indicators for whether the focal *video* earns money for its creator—plot indicators for whether the video's creator appears to *ever* earn money on TikTok. We draw a representative sample of creators who appear in viewers' feeds and scrape all videos they posted from July to September 2025. We estimate their Creator Rewards wage rate in each month by calculating their earnings from videos at least a minute long (imputed from its view count and public information about Creator Rewards' rates) and dividing this by the time spent on all their videos. The latter is calculated using responses to a question in our creator survey about how long it takes to create videos, from creators in the same follower count bin. Reported third-party sponsorship numbers are based on sponsorship, paid-partnership, or advertising tags scraped from the creator's videos. Unreported third-party sponsorship numbers are based on responses to a question in our creator survey about third-party income sources that do not show up in official tags, such as unreported sponsorships or videos made and posted on a sponsor's account rather than the creator's own. We use average responses from creator-survey responses in the same follower bin. The orange bars aggregate over the preceding three bars.

Appendix Figure A30: *Creators who earn money: scraped posting histories versus the creator survey*

Note: The orange bars in this figure replicate those in Figure A29. The red bars plot the share of TikTok creators in our creator survey with the same follower count who say they made money or received free products from posting on TikTok in the last three months. We reweight survey respondents so that within each follower count bin, the share with an email address in their bio matches the share of feed occurrences coming from creators with an email address in their bio.

Appendix Table A10: *Creator Survey respondents by follower count*

		Recruited Through		Platform		
	All	Email	Prolific	TikTok	Instagram	X/Twitter
Under 1,000	332	10	308	235	45	52
1,000–9,999	329	61	264	231	56	42
10,000–99,999	176	143	32	167	7	2
100,000–999,999	65	62	3	63	2	0
1,000,000 or More	25	25	0	25	0	0
Respondents	927	301	607	721	110	96

Note: This table shows the distribution of follower counts of respondents to our creator survey, separately by whether they were recruited via Prolific or email and separately by the primary platform they post on.

Appendix Table A11: *Characteristics of Creator Survey respondents*

		Recruited Through		Platform		
	All	Email	Prolific	TikTok	Instagram	X/Twitter

Respondents	117	181			
Emails sent	8,328	8,329			
Joint test, all answers			$\chi^2(8) = 8.0$		0.43

Note: This table uses randomized incentives to check for selection on unobservables into responding to our emailed creator survey invitations (Dutz et al., 2026). We randomized whether each email offered a $5 or $10 Amazon gift card for completion. The first row of the table shows a first-stage effect of this randomization on response rates. The subsequent rows show no difference in average responses to the survey questions from creators in the two conditions, suggesting no selection into responding on unobservables correlated with the characteristics elicited in the survey. The first two columns report unweighted average answers among respondents offered each amount. The third column reports the coefficient on the $10 offer from a regression of the answer on an indicator for being offered $10 and email-wave-by-follower-decile fixed effects.

Social desirability. Panel (b) of Figure 5 plots responses to a question in our creator survey about which considerations influence what content creators choose to make. Creators are given 3 options and asked to allocate 100 points between them in proportion to the importance of those considerations. To gauge the extent to which answers reflect social desirability, we randomize the wording of the three options between two versions intended to flip their perceived social desirability.

In one version, the question and answer options are:

> Consider the following 3 extreme statements:
>
> 1. I only care about the enjoyment I get from creating the kinds of content I love and people seeing it. I wouldn't switch to making other types of content that I loved creating less, even if this meant more views, followers, or monetization.
> 2. I only care about getting views, followers, or view-based creator rewards payments, regardless of what types of content I'm creating. I wouldn't switch to content that would result in fewer views or followers, even if I enjoyed creating it more or could get more third-party monetization.
> 3. I only care about being able to monetize my content through sponsorships, affiliate links, or other types of sales, and I wouldn't switch to making types of content that would make

this harder to do, even if I enjoyed creating it more or could get more views or followers.

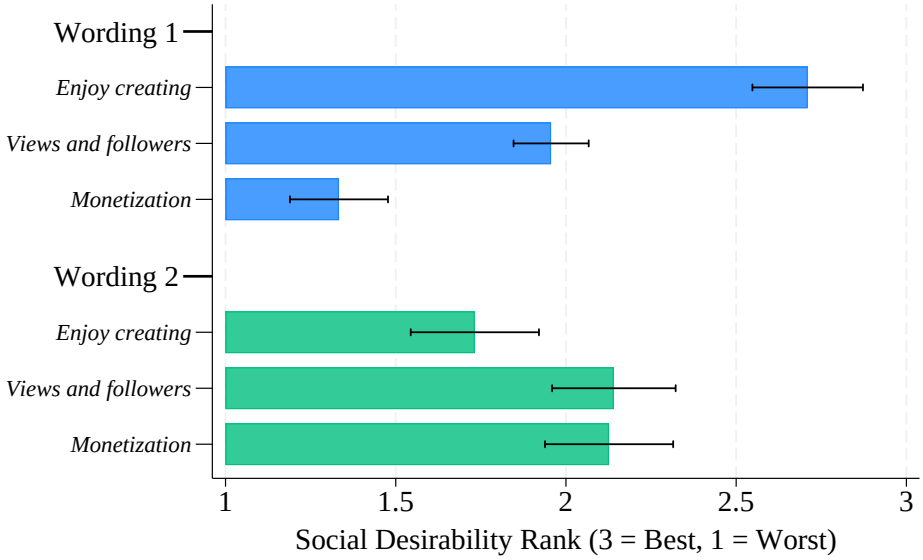

In the flipped version, the three statements are instead:

1. I make content mainly to please myself, and I don't pay much attention to whether they're what people want to read or watch. I wouldn't switch to making other types of content that I'd enjoy less, even if this meant more views, followers, or monetization.
2. What matters most to me is reaching and entertaining as large an audience as I can—views, followers, and view-based creator rewards. I wouldn't switch to content that would result in fewer views or followers, even if I enjoyed creating it more or could get more third-party monetization.
3. I treat this as a real job and focus on building third-party income I can support myself and my family on—through sponsorships, affiliate links, or other sales. I wouldn't switch to content that would make this harder, even if I enjoyed creating it more or could get more views or followers.

In both versions, creators then read: "Most people fall somewhere between these extremes. If you had to allocate 100 points indicating how much you agree with each statement, how would you do it? For example, allocating 100 points to one statement means you fully agree with that statement and do not agree at all with the others. Allocating 50 points to each of two statements means you agree with those two statements equally, and don't agree at all with the third."

Figure A31 plots results from a supplementary survey of 140 Prolific users. Each respondent was shown one of the two question versions and asked to rank the statements according to "which one makes a creator agreeing with it look best in other people's eyes." The figure shows that our manipulation successfully flips the perceived social desirability of the nonpecuniary "enjoyment" reward compared to the pecuniary views/monetization rewards.

Appendix Figure A31: *Perceived social desirability of the creator survey's content-choice statements*

F Model: Proofs and Extensions

F.1 Discussion of assumptions

We discuss the interpretation of, and factual basis for, several of the assumptions we made in setting up our model of social media.

Interpreting Goldman's Law. We have assumed that content production is an unpredictable process: a creator producing a piece may target a general region of the content space, but the final characteristics of the piece—and hence its appeal to potential viewers—emerge with some randomness, captured by the stochastic $q_p + e_{ip}$.

We motivated this assumption by discussing "Goldman's Law" from the literature on media economics (Caves, 2003). An additional stylized fact from this literature is that viewer preferences exhibit extreme heterogeneity: for example, different evaluators' assessments of media correlate only very weakly for movies (Wallisch and Whritner, 2017), images (Vessel and Rubin, 2010), jokes (Rosenbusch et al., 2022), and poems (Belfi et al., 2018).

These facts both arguably stem from the impossibility of tracing the experiences evoked by media to a small set of identifiable dimensions of content (Sibley, 1959). Pieces of media succeed when viewers find them funny, moving, suspenseful, or transporting, reactions produced by collisions between subtle characteristics of the media and consumers' personal traits.

An alternative interpretation of the empirical regularities underlying Goldman's Law is that they reflect behavioral cascades created by herding or strategic complementarities in consumption (Salganik et al., 2006; Gilchrist and Sands, 2016). As long as the property of "being good enough to generate such cascades" is distributed in an ex-ante unpredictable way, our results, which are about how additional production scale

generates additional shots at success, will go through. Moreover, several facts support the interpretation that Goldman's Law reflects ex-ante unpredictability of the intrinsic appeal of pieces of media (Waldfogel, 2019). First, the Law holds in settings where herding and strategic complementarities are likely strong, such as movie sales and repost-based platforms like X/Twitter. But it holds with equal strength in settings where they are likely much weaker, such as TikTok, where reposting plays almost no role and viewers' feeds differ dramatically from their friends'. Indeed, Appendix Figure A2 shows that in our viewership experiment, hiding the "like" counts of TikTok videos does not change the slope of engagement with respect to video popularity. Second, the Law holds for final consumption outcomes but also at earlier steps in the production process. For example, it is very hard to predict whether a script will turn into a movie liked by executives or test audiences (Goldman, 1983). Third, if new pieces of media did not have unpredictable intrinsic appeal, methods such as the TikTok algorithm of discovering underlying appeal would have little commercial value.

The role of unpredictability and heterogeneity. The key function of unpredictability and preference heterogeneity in the model is to increase the returns to production *scale*. The greater the ex-ante unpredictability of the vertical quality of pieces of media, the higher the returns to producing many pieces and ex-post cherry-picking the best ones. Similarly, the greater the heterogeneity of viewer preferences, the higher the returns to procuring many pieces so as to find each viewer pieces close to their personal ideal point.

Note that preference heterogeneity does not need to be ex-ante unpredictable in order to increase the returns to production scale. Instead of the stochastic e_{ip}, we could represent preference heterogeneity in our model with a deterministic viewer-creator match value e_{ij} and derive similar results. These two modelling choices yield essentially the same results and will be empirically indistinguishable given the variation we later generate, so we adopt the stochastic e_{ip} formulation for simplicity.

Algorithmic markups. We have assumed that the platform profits equally from consumption of all content types conditional on their effect on immediate viewer surplus. In principle, the platform may wish to apply an algorithmic "markup" δ_k to certain types of content, serving them to viewers whenever $u_{ip} \geq t_{ik(p)} - \delta_k$, if consumption of those types raises its profits beyond immediate viewer surplus. For example, this would be the case if consuming those types has positive spillover effects on future consumption or engagement with advertisements (Becker and Murphy, 1988, 1993), or if creators of that type particularly value viewership and increasing the reach of their content encourages them to produce. We show in Appendix D that such algorithmic markups can be detected observationally using a method following Kleinberg et al. (2018) and Rambachan (2024). The idea is that if a content type enjoys a markup, viewers' engagement with marginal posts of that type in their feeds should be predictably lower than for marginal posts of other types. We find that advertisements and sponsored videos are algorithmically marked up according to this measure, as expected, but find no evidence of algorithmic markups favoring any of our content types of interest.

Competition between platforms. For simplicity we consider a monopolist platform. Because the mechanisms we are interested in operate through Coasean surplus maximization rather than some kind of rent-shifting that could be undermined by competition, our results are robust to allowing perfect competition.

Wage discrimination. Our results are also robust to type-specific wages, as shown by the modified version of Proposition 1 below. Broadly speaking, type-specific wages will attenuate but not directionally reverse

the effects of increases in μ_k on equilibrium consumption of content type k. This is because higher μ_k, by increasing production of type k, strengthens the "monopsony" force pushing towards lower optimal wages (the fact that higher wages necessitate larger payments to inframarginal producers). This will result in lower wages which slightly offset the initial increase in production.

Proposition 1′. At any vector of wages $\boldsymbol{w} = \{w_k\}_k$, equilibrium consumption shares are a fixed point that can be characterized as follows. Begin by stipulating a vector of cutoffs $\boldsymbol{\tau} = \{\tau_i\}_i$ for appearing in each viewer's feed and a vector $\boldsymbol{h} = \{h_{ik}\}_{i,k}$ of shares of each content type in each viewer's feed.

1. **(Demand)** A creator from group g producing type k faces a cumulative distribution D_{kg} of potential views that depends only on demand-side parameters and equilibrium cutoffs and shares:
$$D_{kg}(v, \boldsymbol{\tau}, \boldsymbol{h}) = \mathbb{P}_{(\{e_i\}_{i\in I}, q)\sim F_{kg}}\left[\sum_{i\in I} \mathbb{1}\{m_k + \widetilde{m}_{ik} + q + e_i - 2\gamma h_{ik} \geq \tau_i\} \leq v\right]$$
2. **(Supply)** The supply of pieces of type k from group g can be written as a function $S_{kg}(\boldsymbol{D})$ of the viewership distribution $\boldsymbol{D} = \{D_{kg}\}_{k,g}$, where $S_{kg}(.)$ depends only on supply-side parameters and wages:
$$S_{kg}(\boldsymbol{D}) = \int_{\{j:\, g_k(j)=g\}} \frac{\exp\left(\psi(\mu_k + \widetilde{\mu}_{jk} + \mathbb{E}_{D_{kg_k(j)}}[\beta V^\rho + w_k V])\right)}{1 + \sum_\ell \exp\left(\psi(\mu_\ell + \widetilde{\mu}_{j\ell} + \mathbb{E}_{D_{\ell g_\ell(j)}}[\beta V^\rho + w_\ell V])\right)}\, dj$$
3. **(Consumption shares)** Consumption of type k can be written as a function of supply and demand:
$$C_k = \sum_g S_{kg}(\boldsymbol{D}) \mathbb{E}_{D_{kg}}(v)$$
Aggregate consumption results from a vector of individual consumption $\{C_{ik} = \sum_g S_{kg}(\boldsymbol{D})\, \mathbb{P}_{F_{kg}}[m_k + \widetilde{m}_{ik} + q + e_i - 2\gamma h_{ik} \geq \tau_i]\}_{i,k}$ generating the stipulated vectors of cutoffs and feed shares: $\tau_i = \underline{u}_i(\sum_\ell C_{i\ell}) - \gamma \sum_\ell h_{i\ell}^2$ and $h_{ik} = C_{ik}/\sum_\ell C_{i\ell}$ for all i, k.

The proof is identical to that of Proposition 1, replacing w with w_k in the payoff of a creator producing type k. Wages do not enter D_{kg} because the platform ignores them when assigning posts.

F.2 Proofs

Proof of Lemma 1. We work backwards from the last step of the game, proving each statement in the lemma and then proving equilibrium existence.

Statement 1. Fix any viewer i and any pool of produced pieces and suppress the subscript i for convenience. Let N_k be the mass of produced pieces of type k and define $U_k(n_k)$ as the focal viewer's total utility from the best n_k pieces of type k. Note that $U_k(.)$ is concave and that because the distribution of utility is atomless, this concavity is strict.

Let $c(\boldsymbol{n})$ denote the total cost to the viewer—combining her opportunity cost of time and boredom cost from diminishing marginal utility—of consuming a feed with $\boldsymbol{n} = \{n_k\}_k$ pieces of each type. Then:
$$c(\boldsymbol{n}) = \gamma \sum_k \frac{n_k^2}{\sum_k n_k} + \int_0^{\sum_k n_k} \underline{u}(t)\, dt \tag{7}$$

Notice that this depends only on the number of pieces of each type. The utility-maximizing feed given $\boldsymbol{n}$ therefore obviously picks the user's favorite n_k pieces of each type and the user's resulting utility is $\sum_k U_k(n_k) - c(\boldsymbol{n})$.

The problem of finding the user's utility-maximizing feed therefore reduces to solving $\max_{\boldsymbol{n}} \sum_k U_k(n_k) - c(\boldsymbol{n})$ for $\boldsymbol{n} \in \Pi_k[0, N_k]$, where N_k is the produced mass of each type. The function being maximized is continuous on a compact set. $U_k(.)$ is strictly concave as previously established, and the components of $c(\boldsymbol{n})$ are convex (the latter term because $\underline{u}(.)$ is increasing), so the function being maximized is also strictly concave. It therefore has a unique maximizer $\boldsymbol{n}^*$, which yields a unique P^*.

To establish the inequality in the statement, notice that:

$$\frac{\partial c}{\partial n_k} = \gamma\big(2h_k - \sum_\ell h_\ell^2\big) + \underline{u}\big(\sum_k n_k\big) = \tau + 2\gamma h_k = t_k \tag{8}$$

The marginal cost of adding a type-k piece to the feed is t_k. This means the marginal piece of each type in the feed has $u_p = t_k$.

Statement 2. By the result above, the viewership of piece p is $v_p = \sum_i \mathbb{1}(u_{ip} \geq t_{ik})$. Since each creator j is infinitesimal and their production decisions hence cannot move viewers' cutoffs, creator j's expected payoff from producing type k before cost shocks and holding fixed the behavior of other creators, is:

$$\bar{\pi}_{jk} = \mu_k + \widetilde{\mu}_{jk} + \mathbb{E}_{F_{kg}}\left[\beta v_p^\rho + w v_p\right] \tag{9}$$

Her corresponding payoff from not producing is zero. The standard logit formula then immediately gives $\sigma_{jk} = \frac{\exp(\psi \bar{\pi}_{jk})}{1+\sum_\ell \exp(\psi \bar{\pi}_{j\ell})}$.

Statement 3. Let $W(w)$ and $V(w)$ be total viewer surplus and total viewership at wage w, respectively. The platform's profit is then $W(w) - wV(w)$ and an interior profit-maximizing solution satisfies the first-order condition $W'(w^*) = V + w^*V'(w^*)$. The right-hand side is the right-hand side of the equation in the lemma. It remains to unpack the left-hand side.

Because we have assumed the platform ignores w when assigning feeds to viewers, w affects $W(w)$ only through the pool of produced content. Imagine we add to this pool a mass ε of type-k pieces that each give viewer i utility u. By the envelope theorem, viewer i's surplus rises to first order by $\varepsilon(u - t_{ik})^+$. The same is true for removing masses of pieces. Since raising w affects creator j's production of type k at rate $\frac{d\sigma_{jk}}{dw}$ and creator j's pieces are drawn from F_{kg}, we get:

$$W'(w^*) = \int_J \sum_k \frac{d\sigma_{jk}}{dw}\, \mathbb{E}_{F_{kg}}\Big[\sum_i (u_{ip} - t_{ik})^+\Big]\, dj \tag{10}$$

Existence of equilibrium. To begin with, fix some $w \geq 0$. Let $\boldsymbol{Q} := \{Q_{kg}\}_{k,g}$ be any set of masses of type-k posts produced by groups g. Note that $\boldsymbol{Q}$ lies in a compact, convex set. The proofs of Statements 1 and 2 demonstrated mappings from $\boldsymbol{Q}$ to viewer feeds and from viewer feeds to a new $\boldsymbol{Q}$, respectively.

Moreover, these mappings are continuous. Each viewer's utility-maximizing $\boldsymbol{n}_i$ is the unique maximizer of a function over $\Pi_k[0, N_k(\boldsymbol{Q})]$ that is continuous in $\boldsymbol{n}_i$ and $\boldsymbol{Q}$, so it and the cutoffs t_{ik} are continuous in $\boldsymbol{Q}$. Since utilities are atomless, the probability that a piece lands in any given set of feeds is continuous in

the cutoffs t_{ik}. Since views take finitely many values, $\bar{\pi}_{jk}$ and the logit probabilities are continuous too.

Brouwer's fixed point theorem then gives an equilibrium $\boldsymbol{Q}$ at each w.

So it remains to be shown that the platform has an optimal w. The same arguments as above show that W and V are continuous in $\boldsymbol{Q}$ and that the set of $(w, \boldsymbol{Q})$ pairs where $\boldsymbol{Q}$ is an equilibrium under w is closed. Note there is some positive constant $\underline{V}$ that bounds total viewership from below at every wage. Also, for some $\overline{W}$, for any $\boldsymbol{Q}$, $W(\boldsymbol{Q}) \leq \overline{W}$. Thus any $w > \overline{W}/\underline{V}$ yields negative profit and performs strictly worse than $w = 0$. The platform's profit $W(\boldsymbol{Q}) - wV(\boldsymbol{Q})$ is therefore continuous on a compact set of $(w, \boldsymbol{Q})$ pairs with $w \leq \overline{W}/\underline{V}$, so it has a maximizer $(w^*, \boldsymbol{Q}^*)$, which gives an equilibrium.

□

Proof of Proposition 1. Fix any wage w. We start by showing that any equilibrium at w generates a fixed point of the kind described in the proposition. We then show that any such fixed point describes an equilibrium at w.

Notationally, we will let Q_{kg} denote the mass of type-k pieces produced by group g and $Q_{kg}\mathbb{P}_{F_{kg}}[A]$ the mass of produced pieces satisfying an arbitrary condition A on the q and e_i draws.

We begin with demand. Fix an equilibrium at w and let τ_i and h_{ik} be the attention prices and feed shares in this equilibrium. By Lemma 1, viewer i sees piece p of type k if and only if:

$$m_k + \widetilde{m}_{ik} + q_p + e_{ip} - 2\gamma h_{ik} \geq \tau_i \tag{11}$$

A piece's views v_p are the number of viewers i for whom this inequality holds. So the views of a piece of type k created by a creator from group g are distributed according to $D_{kg}(., \boldsymbol{\tau}, \boldsymbol{h})$ as described in the proposition.

Next, consider supply. By Lemma 1, a creator j producing type k as a member of group g expects utility $\mathbb{E}_{F_{kg}}[\beta v_p^\rho + w v_p]$ from views, which we can rewrite as $\mathbb{E}_{D_{kg}}[\beta v_p^\rho + w v_p]$. Substituting into the logit formula from Lemma 1 and integrating over creators yields $Q_{kg} = S_{kg}(\boldsymbol{D})$ as defined in the proposition.

Finally, consider consumption shares. Viewer i's feed contains all pieces of type k satisfying Inequality (11). A total mass $S_{kg}(\boldsymbol{D})\mathbb{P}_{F_{kg}}[m_k + \widetilde{m}_{ik} + q_p + e_{ip} - 2\gamma h_{ik} \geq \tau_i]$ satisfy this inequality. Summing over g gives viewer i's consumption C_{ik} and summing over viewers gives $C_k = \sum_g S_{kg}(\boldsymbol{D})\mathbb{E}_{D_{kg}}(v)$.

The total consumption of viewer i is $T_i = \sum_\ell C_{i\ell}$, so it follows by definition that $h_{ik} = \frac{C_{ik}}{\sum_\ell C_{i\ell}}$ and by Lemma 1 that $\tau_i = \underline{u}_i(\sum_\ell C_{i\ell}) - \gamma \sum_\ell h_{i\ell}^2$.

So this equilibrium is a fixed point of the kind described in the proposition. It remains to show that any such fixed point is an equilibrium.

Take any fixed point $(\boldsymbol{\tau}, \boldsymbol{h})$ generating $\boldsymbol{D}$ and suppose creators' production decisions are described by $S_{kg}(\boldsymbol{D})$ and each viewer i receives the feed P_i of pieces satisfying Inequality (11). To demonstrate this is an equilibrium, we first show that P_i maximizes viewer i's utility and then that creator production decisions are optimal in expectation.

Note that P_i contains C_{ik} type k pieces and its total mass is $\sum_\ell C_{i\ell}$ and shares of each type of h_{ik}. Hence as in the proof of Lemma 1, the marginal cost of adding a piece of type k is $\tau_i + 2\gamma h_{ik}$. By Inequality (11), each piece of type k in P_i offers utility exceeding this cost and each piece of type k outside P_i falls below

this threshold. This means no small change in any C_{ik} can raise i's utility. Since $\sum_k U_k(n_k)$ is additively separable across content types, we are at a local optimum. Since, as we established earlier, i's utility is concave in the masses composing $\boldsymbol{n}_i$, P_i must be globally optimal.

Given this, each type k piece made by a creator of group g has an expected distribution of views given by D_{kg}, so such a creator's expected utility from producing this type is exactly as in $S_{kg}(\boldsymbol{D})$ and the S_{kg} logit probabilities represent her best response.

This means both production and consumption form an equilibrium at w given that they satisfy the fixed-point property in the proposition.

□

Proof of Proposition 2. We start by showing how to characterize equilibria as fixed points of a one-dimensional mapping. This then allows us to prove each statement in the proposition.

Preliminary step: equilibria as fixed points of a mapping.

Normalize the mass of creators to one; since we have assumed each creator produces one piece, a unit mass of pieces is produced. Let α denote the share of produced pieces that are type H and let $\Delta := m_H - m_L$. Write $q_p + e_{ip} = s\xi_{ip}$ for some scalar $s > 0$ and $\{\xi_{ip}\}_{i\in I}$ drawn from some joint distribution. Let $\bar{G}_i(x) := \mathbb{P}(\xi_{ip} \geq x)$ and let $r(v) := \beta v^\rho + wv$ be a shorthand for rewards from viewership. $\bar{G}$ is continuous by our earlier assumptions. Let n be the number of viewers.

By Lemma 1 and setting $\gamma = 0$, viewer i watches the pieces p satisfying $u_{ip} \geq \tau_i$ where the τ_i threshold adjusts so that exactly T_i posts clear it. Let $x_i := \frac{\tau_i - m_L - \widetilde{m}_i}{s}$. Then viewer i watches a piece of L content exactly when $\xi_{ip} \geq x_i$ and a piece of H content exactly when $\xi_{ip} \geq x_i - \frac{\Delta}{s}$. Let $P_{iL} := \bar{G}_i(x_i)$ and $P_{iH} := \bar{G}_i(x_i - \frac{\Delta}{s})$ be the probabilities with which she watches a random produced L or H piece, respectively.

Since the viewer consumes T_i posts, we can write:

$$T_i = (1-\alpha)P_{iL} + \alpha P_{iH} \tag{12}$$

Fix any $\alpha \in (0,1)$ and suppose that $T_i < 1$. (Everything that follows will hold trivially for a viewer with $T_i = 1$ who consumes all produced content.) The RHS of Equation 12 is continuous, decreasing in x_i, and ranges between 0 and 1, so a unique P_{iL}, P_{iH} solution exists. This P_{iL} and P_{iH} are continuous in α and $\frac{\Delta}{s}$ since $\bar{G}_i$ is continuous.

We make two observations. First, holding α fixed, increasing $\frac{\Delta}{s}$ decreases P_{iL} and increases P_{iH}. Second, holding $\frac{\Delta}{s}$ fixed, increasing α reduces both P_{iL} and P_{iH}, since $P_{iH} \geq P_{iL}$ always.

Now observe that a piece that draws the shock vector $\{\xi_i\}_{i\in I}$ receives $V_L := \sum_i \mathbb{1}\{\xi_i \geq x_i\}$ views if it is an L piece and $V_H := \sum_i \mathbb{1}\{\xi_i \geq x_i - \frac{\Delta}{s}\}$ views if it is an H piece, with $V_H \geq V_L$ for all shock vectors. Let $R_k := \mathbb{E}\big(r(V_k)\big)$ be a creator's expected reward from viewership when producing a piece of type k. Notice that if P_{ik} rises for each i, then V_k rises for almost every shock draw and therefore R_k rises.

Since each creator always produces either an L or H piece and creators are homogeneous, the logit formula from Lemma 1 gives:

$$\frac{\alpha}{1-\alpha} = \exp(\psi(\mu_H - \mu_L + R_H - R_L)) \tag{13}$$

This means α is an equilibrium exactly when:

$$\alpha = \Gamma(\alpha) := \Lambda\big(\psi(\mu_H - \mu_L + R_H - R_L)\big), \qquad \Lambda(z) := \frac{e^z}{1+e^z} \tag{14}$$

and $R_H - R_L$ is evaluated at the viewing probabilities induced by α. By the observations above, Γ is continuous on $(0,1)$, and since $0 \le R_H - R_L \le r(n)$, it takes values in $[a,b]$, where $a := \Lambda(\psi(\mu_H - \mu_L)) > 0$ and $b := \Lambda(\psi(\mu_H - \mu_L + r(n))) < 1$. So $\Gamma(\alpha) > \alpha$ for $\alpha < a$ and $\Gamma(\alpha) < \alpha$ for $\alpha > b$.

It follows that there exist highest and lowest equilibria $\overline{\alpha}$ and $\underline{\alpha}$ which satisfy:

$$\overline{\alpha} = \max\{\alpha \in (0,1) : \Gamma(\alpha) \ge \alpha\} \quad \text{and} \quad \underline{\alpha} = \min\{\alpha \in (0,1) : \Gamma(\alpha) \le \alpha\} \tag{15}$$

Consider the first set. It contains $(0,a]$, is contained in $(0,b]$, and is closed in $(0,1)$ by continuity, so it has a maximum α^*. If $\Gamma(\alpha^*) > \alpha^*$, then since $\Gamma(\alpha) < \alpha$ for $\alpha > b$, the intermediate value theorem gives a fixed point above α^*, which belongs to the set, a contradiction. So α^* is a fixed point, and since every fixed point belongs to the set, it is the highest fixed point. The argument for $\underline{\alpha}$ is symmetric.

Equation (15) is what delivers our comparative statics. If a change in parameters lowers $\Gamma(\alpha)$ at every α, the first set in Equation (15) shrinks and the second grows, so both $\overline{\alpha}$ and $\underline{\alpha}$ fall. Similarly, if it raises $\Gamma(\alpha)$ at every α, both rise.

We can now move on to proving the statements. In each, we use α to refer to either $\overline{\alpha}$ or $\underline{\alpha}$.

Statement 1. First consider production. Fix any α. Increasing s mechanically lowers $\frac{\Delta}{s}$, which as stated earlier raises P_{iL} and lowers P_{iH} for every viewer i. R_L therefore increases and R_H decreases, so $\Gamma(\alpha)$ decreases. Since this is true at every α, H's equilibrium production share α decreases.

Now consider consumption. By Equation (12), the share of type H in viewer i's consumption is $h_i := \frac{\alpha P_{iH}}{T_i} = 1 - \frac{(1-\alpha)P_{iL}}{T_i}$. Increasing s decreases both $\frac{\Delta}{s}$ and α, both of which work to increase P_{iL}. Since $1-\alpha$ also increases, h_i falls. This holds for each viewer i, so the aggregate H consumption share decreases.

Statement 2. This is immediate. Creators' total utility from wages is $w\sum_i T_i$, and creators' total intrinsic utility is $(1-\alpha)\mu_L + \alpha\mu_H > 0$. Hence:

$$R(s) = \frac{w\sum_i T_i}{(1-\alpha)\mu_L + \alpha\mu_H} \tag{16}$$

The numerator does not depend on s, and the denominator increases with s because α decreases with s as observed earlier and $\mu_L > \mu_H$.

Statement 3. Fix a viewer i. The T_i produced pieces with the highest $q + e_i$ draws are those with $\xi_{ip} \ge z_i$, where $\bar{G}_i(z_i) = T_i$.Take any piece p and let $\xi := \xi_{ip}$. For a random produced piece p', we have:

$$\mathbb{P}\big[|(q_p + e_{ip}) - (q_{p'} + e_{ip'})| < \Delta\big] = \mathbb{P}\Big[\xi - \frac{\Delta}{s} < \xi_{ip'} < \xi + \frac{\Delta}{s}\Big] \tag{17}$$

which is obviously decreasing in s. This is true for every ξ, and in particular for every $\xi \ge z_i$.

Statement 4. Let θ denote the focal parameter out of β, ρ, or w. Start with production. Fix any α. Since

$V_H \geq V_L$,

$$r(V_H) - r(V_L) = \beta(V_H^\rho - V_L^\rho) + w(V_H - V_L) \tag{18}$$

is increasing in β, w, and ρ. So raising θ raises $R_H - R_L$ and therefore $\Gamma(\alpha)$. Since this is true at every α, H's equilibrium production share α rises.

Now consider consumption. Increasing θ leaves $\frac{\Delta}{s}$ unchanged and raises α, which as observed earlier lowers P_{iL}. Since $1 - \alpha$ also falls, $h_i = 1 - \frac{(1-\alpha)P_{iL}}{T_i}$ increases for every viewer i, and therefore so does the aggregate H consumption share.

□

F.3 Short-form content

We write a short toy model formalizing the observations in Section 2.2 about why the social media business model complements short-form content.

Consumption of short and long content. For simplicity, we consider a single content type with a baseline appeal m and joint distribution F from which q and e shocks are drawn. *Subunits* of content are the smallest units over which the q and e shocks are realized. Viewer i's utility from subunit p is $u_{ip} = m + q_p + e_{ip}$.

A piece of content can be *short*, consisting of a single subunit, or *long*, consisting of two subunits with independently drawn q and e shocks. Each viewer has a feed with two slots. A viewer's utility from a feed is her utility from the two subunits in the feed, plus χ if both subunits were part of the same long piece. χ can be positive, representing a preference for coherence, or negative, representing a preference for variety.

Production of short and long content. Pieces of content are produced by a finite number of homogeneous potential creators. Each creator chooses between producing nothing, producing a short piece, or producing a long piece, and draws independent logit shocks for each option from a common distribution with scale $1/\psi$.

Producing a piece of length $\ell \in \{1, 2\}$ incurs cost c_ℓ and yields nonpecuniary payoff μ_ℓ. Because creators are ex-ante homogeneous, we can roughly think of μ as subsuming expected utility from viewership.[34]

We allow both costs and rewards to be either concave or convex in length, depending on whether $c_2 < 2c_1$ and likewise whether $\mu_2 < 2\mu_1$. In general, convex costs and concave rewards will favor short-form content on both social and legacy media, and vice versa for concave costs and convex rewards. Because our results are about the *difference* in returns to short-form content *between* legacy and social media, we can remain agnostic between these possibilities.

Outlets' objectives and technological capabilities. As before, we assume outlets maximize expected viewer surplus net of procurement costs. Legacy outlets are unable to observe and act on the q and e shocks when distributing content to viewers, while social media platforms are able to.

Mechanism I: social media benefits more from breaking up produced content. Our first point is immediate. Fix some produced pool containing some number of long units of content and fix a viewer i. Consider whether the outlet wishes to serve viewer i a single long unit or two short subunits. (Either by serving two produced short subunits, or "breaking up" long units into their subunits and serving viewer i subunits from two different long units.)

[34] Technically it should then depend on the number of other creators being recruited, but we abstract away from this for simplicity.

From the perspective of a legacy outlet unable to observe q and e realizations, all subunits are interchangeable. So the outlet will strictly prefer to serve long units when viewers prefer coherence ($\chi > 0$) and strictly prefer to serve pairs of short subunits when viewers prefer variety ($\chi < 0$).

From the perspective of a social media platform, the platform may want to serve viewer i two short subunits even if $\chi > 0$. This will happen if the two highest $q + e$ draws accrue to two subunits that do not belong to the same long unit, and the utility from serving these two subunits exceeds the utility from serving the best long unit by at least χ.

So conditional on a produced pool, social media platforms wish to distribute short-form content in a strictly larger set of cases than legacy outlets.

Endogenizing production. We now endogenize production. Each outlet sets a wage per view and creators make production decisions. Views accrue to subunits, so a long piece served to n viewers receives $2n$ views.

Mechanism II: social media benefits more from reducing barriers to entry. Consider a *minimum length requirement* where the platform refuses to accept short pieces.

Proposition 3. Suppose $q + e$ is nondegenerate and fix a wage.

1. If removing a minimum length requirement reduces total production of subunits, it is not profitable for a legacy or a social media outlet.
2. If doing so increases total production of subunits, the cases where it strictly raises a social media platform's profit are a strict superset of the cases where it raises a legacy outlet's profit.

Removing a minimum length requirement *lowers barriers to entry*, inducing a flow of creators from "produce nothing" to "produce a short subunit." But it can also induce a flow of creators from "produce a long unit" to "produce a short subunit".

If the latter flow outnumbers the former, such that removing a minimum length requirement reduces total production scale, it is never profitable for either type of media.

But suppose that removing a minimum length requirement increases total production scale. This could be because production costs are convex or rewards are concave, but it could also be because there is a large mass of creator taste shocks near the boundary between "produce nothing" and "produce a short unit." For example, it could be the case that production costs are concave in length *but* there are also many people who never have an idea good enough for a long post but occasionally have an idea for a 30-second video or short post and will only post it if minimum requirements are low enough.

In this case, because social media platforms benefit more from production scale than legacy outlets do, social media platforms are more likely to favor removal of the minimum length requirement. (They will not always do so, because if $\chi > 0$ then removing a length requirement can be unprofitable even if it increases total production of subunits.)

Mechanism III: short content improves social media's experimentation step. Throughout the paper so far we have abstracted away from the details of the experimentation step where the platform learns a piece's ex-post distribution of appeal to viewers. Our next mechanism requires us to unpack this step a bit more.

Learning about a piece's potential appeal requires learning about the characteristics of the *piece* and

learning about the preferences of different *viewers*. Short-form content makes the latter easier. If different subunits have different characteristics, long pieces mash together many different characteristics. This makes it hard to learn about a viewer's tastes from her engagement with a long piece because the platform does not know which subunit's characteristics drove the viewer's engagement. Disaggregating pieces into the smallest units over which characteristics vary allows much more efficient learning about viewer preferences. To grasp the intuition, consider how much more TikTok knows about your preferences after you scroll for 10 hours, compared to how much Netflix knows about your preferences after you watch 10 hours of movies or TV. Netflix will not know whether you like a certain show because it has a certain famous actor, or because it is a thriller, or because it is critically acclaimed, or because it is set in London, or because. . .

Formally, suppose each subunit independently and uniformly draws a characteristic $x_p \in \{-1, 1\}$. Viewer i's utility is $u_{ip} = \theta_i x_p + m + q_p + e_{ip}$. Her taste for x_p is given by $\theta_i = \bar{\theta} + \tilde{\theta}_i$ where $\tilde{\theta}_i$ is independent and identically distributed across viewers. $q_p + e_{ip}$ has variance ω^2.

In the experimentation step, the platform serves each viewer a random feed of T subunits and knows the characteristics of all served subunits. If it serves short pieces, it observes T draws of $\theta_i x_p + m + q_p + e_{ip}$ for an expected precision of $\frac{T}{\omega^2}$ about θ_i. If it serves long pieces, it observes $\frac{T}{2}$ draws of $\theta_i(x_a + x_b) + 2m + \chi + q_a + e_{ia} + q_b + e_{ib}$ and ends up with precision $\frac{T}{2\omega^2}$, or half as much precision.

We have focused on learning about viewer preferences given knowledge of piece characteristics. There is also the converse of learning about piece characteristics given knowledge of viewer preferences. But this is less interesting, because if the platform is ultimately *serving* long pieces of content, there is actually no gain to doing the experimentation step with short pieces. At least, this is true in the simple structure we have adopted with additive utility over subunits. Such gains can exist with preferences that are nonadditive over the utility from subunits.

Other mechanisms. In asking why social media content is short-form, we have pitted two classes of explanations against each other. The conventional explanation in the literature is that short-form content hijacks features of our reward psychology just like slot machines do (e.g., Eyal, 2014; Bao, 2026). We have emphasized a class of alternative explanations focused on our characterization of social media's business model as being primarily about ex-post experimentation and cherry-picking.

There are also other explanations that do not fit into either class. For example, smartphones enable people to scroll briefly on social media in their spare minutes. This complements short pieces of content that do not require much context to appreciate and does not fit well with longer pieces of content like hour-long TV episodes where there is some buildup, context-setting, and characterization before "payoffs" arrive.[35] In our data, platforms vary in the extent to which viewers scroll on them briefly. The median minute spent on TikTok is part of a 22-minute session, while the median minute on Instagram is part of a 4.5-minute session.

Evidence on Mechanism I. Mechanism I relies on social media platforms discriminating between different subunits of the same long piece of content because of internal variation in a long piece's vertical quality or horizontal characteristics. The extent to which this kind of variation exists is an empirical question. For example, does somebody who likes one of a comedian's jokes tend to like all the other jokes in the same set? Or does somebody who likes one of a movie's scenes tend to like the others?

[35] We thank Nikhil Agarwal for suggesting this explanation.

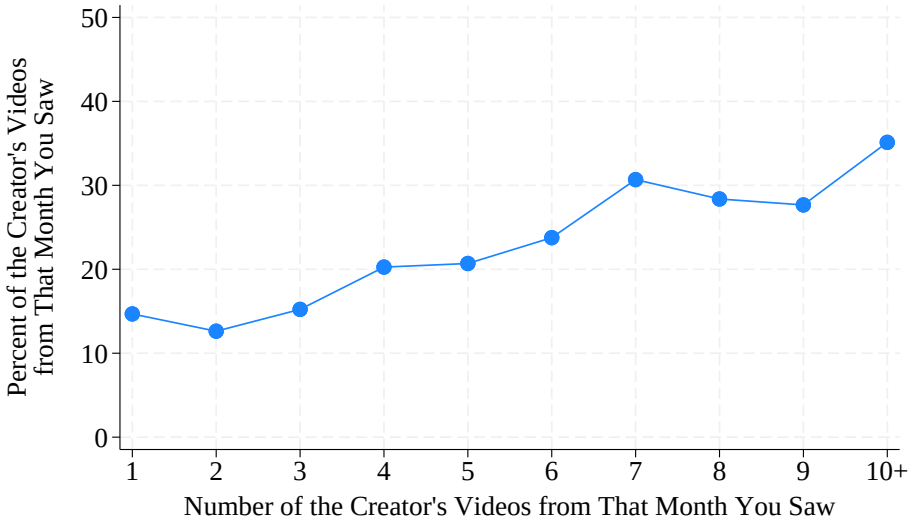

The ideal data for answering these questions consists of measurements of the same person's utility from different subunits of a long piece of content, like their enjoyment of each joke from a comedy set. We can try to approximate this ideal dataset by looking at variation across the different pieces of short content posted by a creator on social media. Does a viewer who likes one of a creator's videos tend to like the others? Do two viewers who both like some of the same creator's videos like the *same* videos as each other?

Figures A32 and A33 show that the TikTok algorithm substantially discriminates in its assignment of videos *within* creator.

Even a viewer who sees ten of a creator's posts in a month—indicating a fairly consistent taste for this creator—is still served only a third of the posts the creator makes over this time period. This suggests discrimination that may be partly about vertical quality: only a third of the creator's posts are high-quality enough to make it into the viewer's feed.

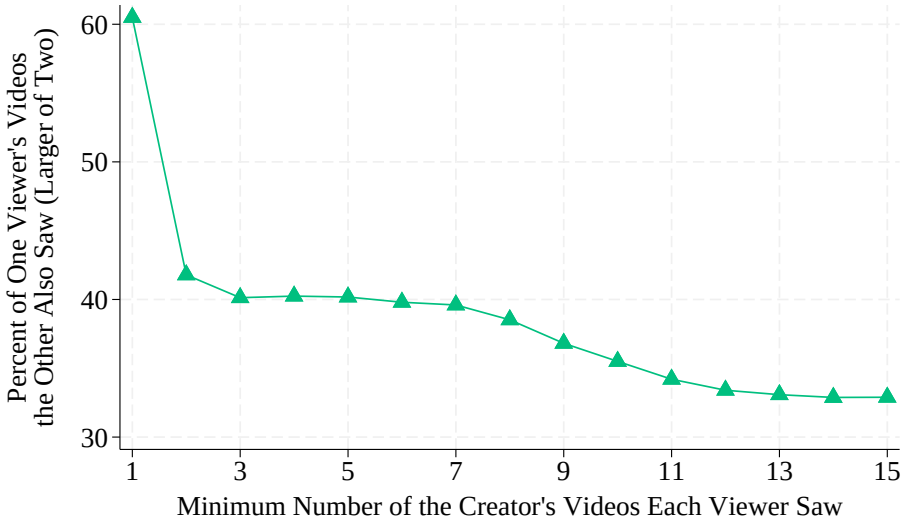

Meanwhile, compare two viewers who both see at least ten posts from the same creator over the same period. The average overlap between the posts each saw is only around 35%—indicating there is also substantial *horizontal* discrimination, with one viewer liking some of a creator's posts and the other viewer liking others.

Appendix Figure A32: *Viewers see only a small share of the videos posted by the creators they watch*

Notes: This figure uses our TikTok viewership histories. For a random sample of creators in these histories we scrape every post they make between July and September 2025 using TikTok's Research API. Conditional on a viewer seeing at least one video from a given creator during this period within three days of the video being posted, the figure plots the share of posts made by the creator in the same month that appear in the participant's feed, as a function of the total number of posts from that creator appearing in the participant's feeds this month. Results are weighted to be representative of the creators appearing in participants' feeds.

Appendix Figure A33: *Two viewers of the same creator see largely different videos from that creator*

Notes: This figure uses our TikTok viewership histories, restricted to a period (August to September 2025) and set of viewership histories such that all histories span the full period. For each pair of participants i and i' and each creator j such that both participants see a video from j, we count n_i (the number of posts i sees from j), $n_{i'}$ (the number of posts i' sees from j), and n_{both} (the number of j's videos seen by both i and i'). The y-axis of this plot shows $100 \times \max\{\frac{n_{\text{both}}}{n_i}, \frac{n_{\text{both}}}{n_{i'}}\}$ and the x-axis shows $\min\{n_i, n_{i'}\}$.

F.4 Discontinuity analysis

This section provides a formal interpretation of the discontinuity results reported in Section 3.4.

Setup. Consider an extension of our model from Section 2. A creator's production decision involves choosing both a content type k and a length ℓ from a finite grid of possible values. Creating a piece of type k at length ℓ incurs cost $c_k(\ell)$. Let $\bar{\ell} = 60$ seconds denote the threshold for Creator Rewards eligibility and $\bar{\ell}^-$ denote the grid point just below 60 seconds.

Creator j draws an independent type-I extreme value shock $\kappa_{kj\ell}$ with scale $1/\psi$ for every pair of content type and length, then decides what to produce. Their expected payoff is:

$$\mu_k + \widetilde{\mu}_{jk} - c_k(\ell) + \mathbb{E}_{D_{kg}}\left[\beta V^{\rho} + w\,\mathbb{1}\{\ell \geq \bar{\ell}\}\,V\right] + \kappa_{jk\ell}.$$

As in Section 2, we assume the platform ignores wages when assigning produced posts to viewers. We also assume a piece's expected viewership distribution D_{kg} does not depend on its length locally around $\bar{\ell}$.

Let $s_k(\ell)$ be the share of produced length ℓ videos that are type k. Define four objects:

1. The discontinuity d_k in log prevalence of type k at $\bar{\ell}$, $d_k := \log s_k(\bar{\ell}) - \log s_k(\bar{\ell}^-)$.
2. The local cost Δc_k of lengthening a type-k video from $\bar{\ell}^-$ to $\bar{\ell}$, $\Delta c_k := c_k(\bar{\ell}) - c_k(\bar{\ell}^-)$.
3. Expected viewership of a piece of type k produced by group g, $W_{kg} := \mathbb{E}_{D_{kg}}[V]$.
4. Expected viewership $\overline{W}$ of type k locally at ℓ^-, averaging across the groups that produce in equilibrium, $\overline{W}_k := \frac{1}{\psi w} \log \sum_g \omega_{kg} \exp(\psi w W_{kg})$, where ω_{kg} is group g's share of type-k videos of length $\bar{\ell}^-$.

Proposition 4. In any equilibrium, take any content types k and k'. Then:

$$d_k - d_{k'} = \psi w\left(\overline{W}_k - \overline{W}_{k'}\right) - \psi\left(\Delta c_k - \Delta c_{k'}\right)$$

In particular, if the local cost of manipulating length is the same across types ($\Delta c_k = \Delta c_{k'}$), then $d_k - d_{k'}$ has the same sign as the expected viewership gap $\overline{W}_k - \overline{W}_{k'}$.

Proof. The choice probability $\sigma_{jk\ell}$ satisfies $\sigma_{jk\bar{\ell}}/\sigma_{jk\bar{\ell}^-} = \exp\left(\psi(wW_{kg} - \Delta c_k)\right)$ for each creator j in group g for type k. The mass of type-k videos at $\bar{\ell}$ therefore equals the mass at $\bar{\ell}^-$ times $\sum_g \omega_{kg} \exp\left(\psi(wW_{kg} - \Delta c_k)\right) = \exp\left(\psi(w\overline{W}_k - \Delta c_k)\right)$. Since $s_k(\ell)$ divides this mass by the total mass of videos of length ℓ, which is common across types, $d_k = \psi(w\overline{W}_k - \Delta c_k) - \log \frac{N(\bar{\ell})}{N(\bar{\ell}^-)}$, where $N(\ell)$ is the total mass of videos of length ℓ. Differencing across types k and k' gives the result. □

More general cost shock distributions. The logit cost shocks in our model make proportional production responses to a fixed payoff increase independent of a content type's baseline production level. This means that comparing *proportional* changes in production prevalence across types identifies rankings of those types according to expected viewership.

Under more general shock distributions, it remains approximately valid to compare content types with similar baseline production levels. But comparisons between types with different production levels are no longer informative.

To see this, consider a more general setup. Suppose each type has only a single creator group. Write the mass of type-k videos of length ℓ as $A \times G(U_k(\ell))$, where:

1. $U_k(\ell) := \mu_k - c_k(\ell) + \mathbb{E}_{D_k}[\beta V^\rho] + w\mathbb{1}\{\ell \geq \bar{\ell}\}\, W_k$ is the expected payoff of producing a piece of type k at length ℓ.
2. G is any strictly increasing function.
3. $A > 0$ is common across types.

Our baseline model is the case where $G = \exp(\psi U_k(\ell))$ and A is the denominator of the logit formula.

Let $p_k := G(U_k(\bar{\ell}^-))$ be type k's production rate just below the length threshold. Let $\phi(p) := G'(U)/G(U)$ evaluated at $G(U) = p$ be the semi-elasticity of production with respect to payoffs. In our model, $\phi = \psi$.

Proposition 5. Suppose the local cost of manipulating length is the same across types. For any types k and k':

1. If their baseline production levels are the same, $p_k = p_{k'}$, then for any G, $d_k - d_{k'}$ has the same sign as $W_k - W_{k'}$.
2. If G is log-concave, $p_k \geq p_{k'}$, and $d_k > d_{k'}$, then $W_k > W_{k'}$.

Proof. Write $U_k := U_k(\bar{\ell}^-)$ and $\Lambda(U, x) := \log G(U + x) - \log G(U)$. With common Δc, $d_k - d_{k'} = \Lambda(U_k, wW_k - \Delta c) - \Lambda(U_{k'}, wW_{k'} - \Delta c)$. Λ is strictly increasing in x.

1. $p_k = p_{k'}$ implies $U_k = U_{k'}$, so $d_k - d_{k'}$ has the same sign as $W_k - W_{k'}$.

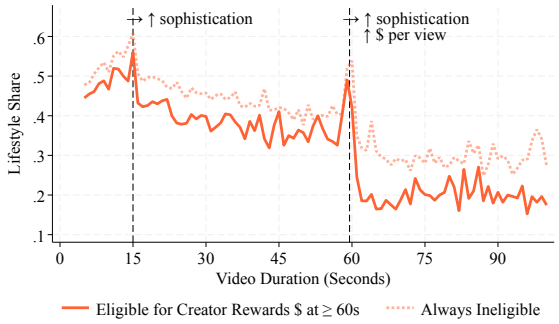

2. Log-concavity makes Λ weakly decreasing in U, and $p_k \geq p_{k'}$ implies $U_k \geq U_{k'}$. If $W_k \leq W_{k'}$, then $\Lambda(U_k, wW_k - \Delta c) \leq \Lambda(U_k, wW_{k'} - \Delta c) \leq \Lambda(U_{k'}, wW_{k'} - \Delta c)$, contradicting $d_k > d_{k'}$.

□

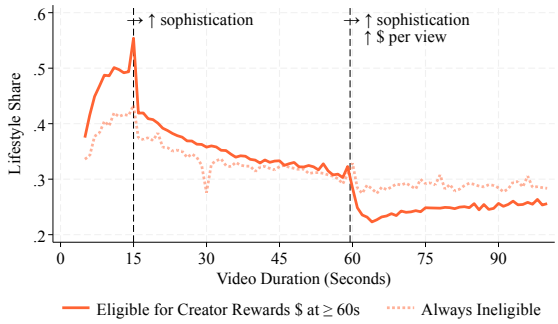

Since the baseline production rates of lifestyle and entertainment are similar (0.31 and 0.35), our results comparing them are robust. Comparisons of partisan and nonpartisan content are less robust, as partisan content is about 65% of political production.

Appendix Figure A34: *Discontinuities in content by video length, separately for each sample and content measure*

(i) *Politics, random sample, median views*

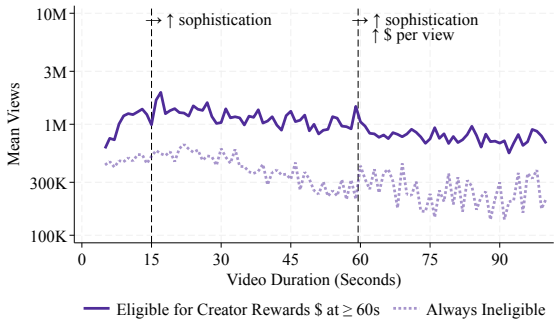

(j) *Politics, viewing histories, median views*

(k) *Politics, random sample, mean views*

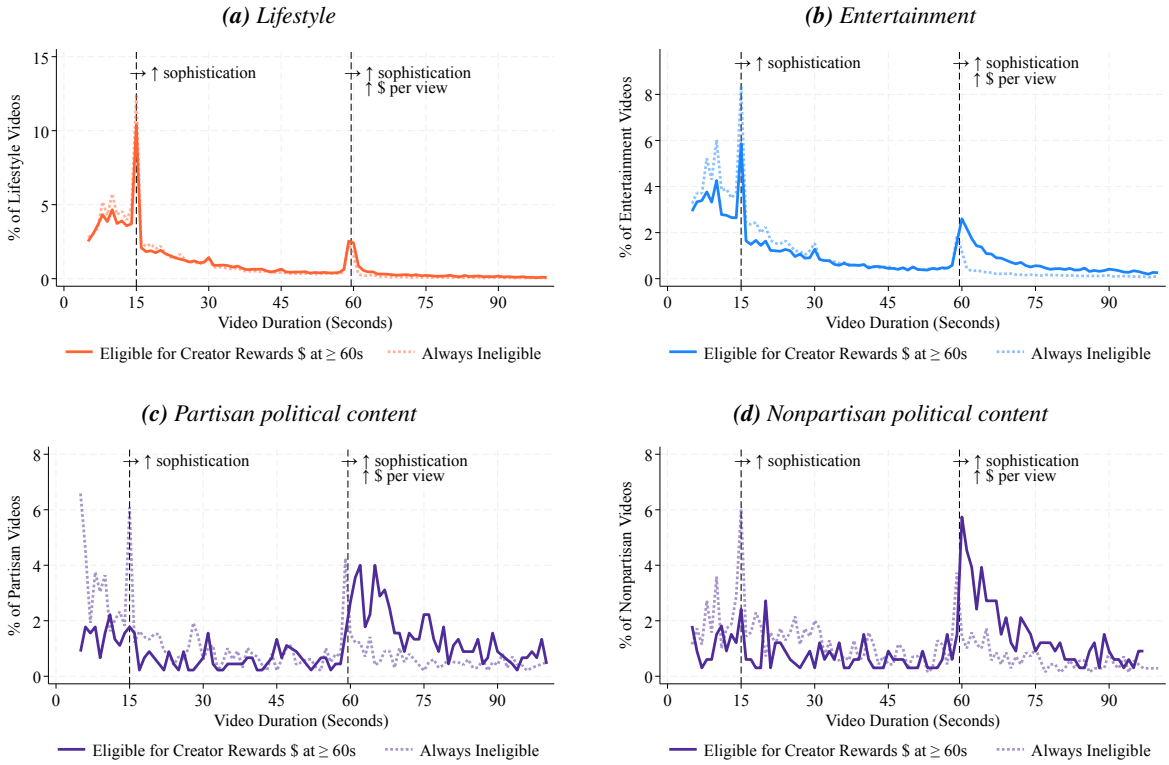

(l) *Politics, viewing histories, mean views*

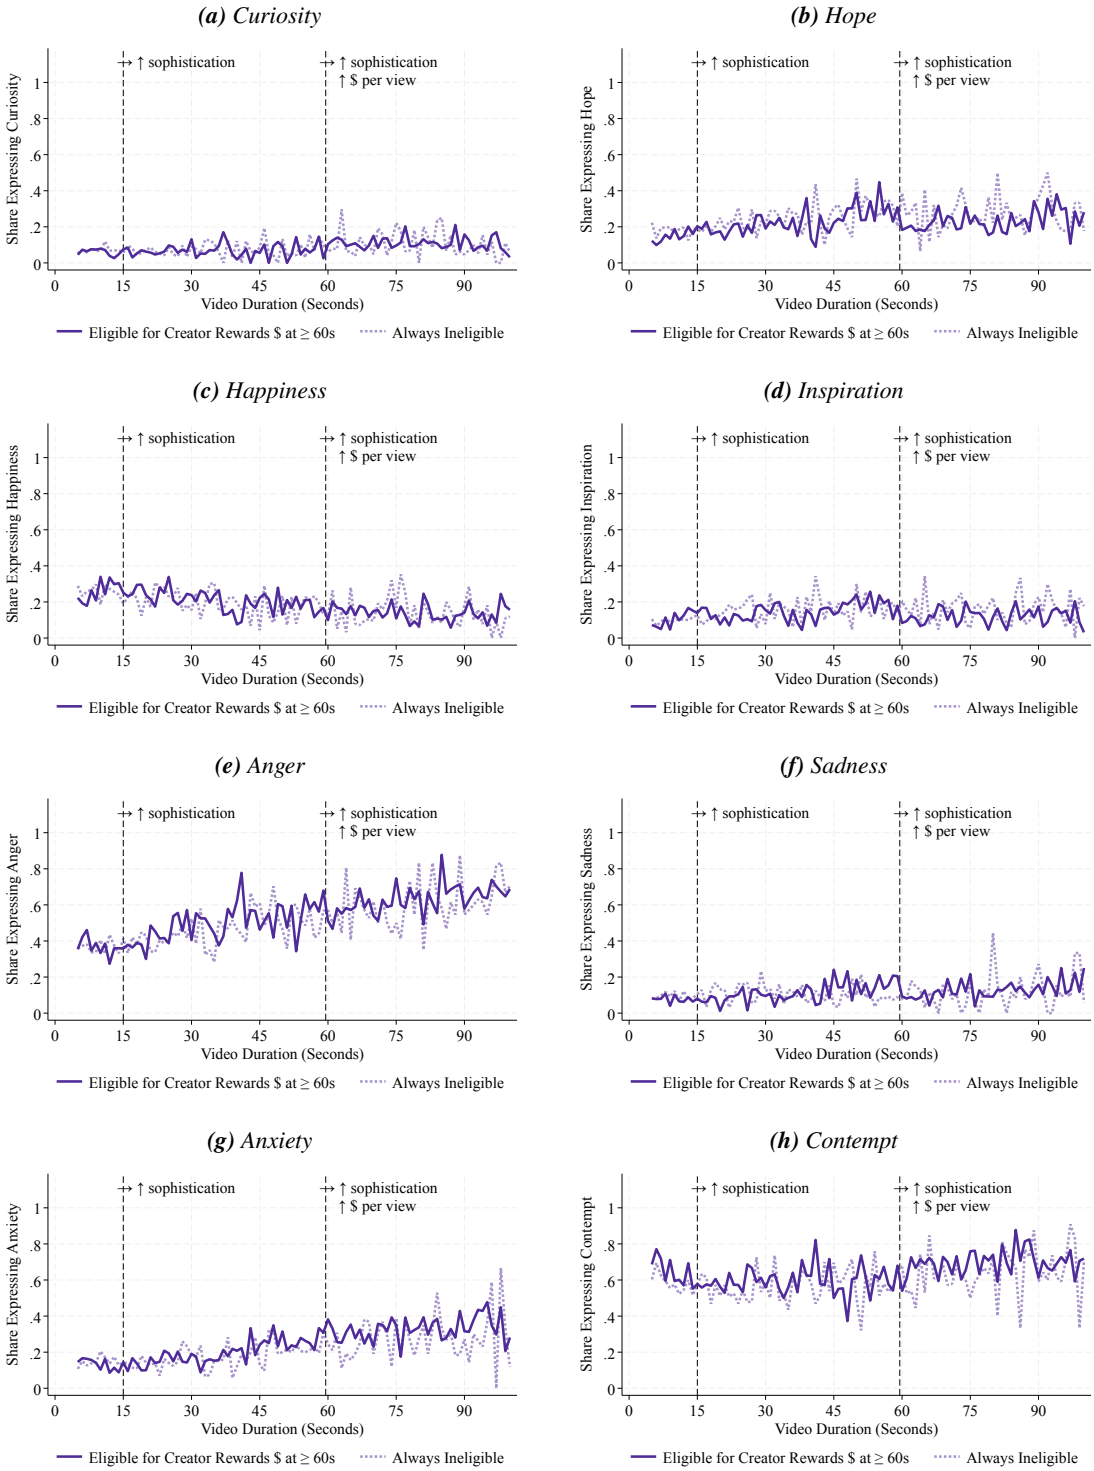

Notes: This figure plots views per video by video length. The left column uses the pool of videos randomly sampled from the Research API and the right column uses the videos in our viewership histories. Both columns use classifications predicted from our machine-learning classifier trained on a set of GPT-coded videos.

Appendix Figure A36: *Production density by video length for each content type*

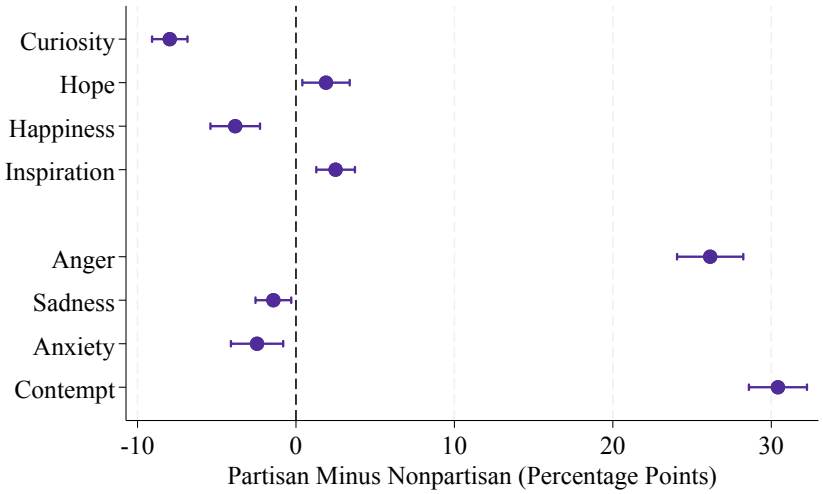

Notes: This figure plots the density of video lengths for each content type using our pool of videos randomly sampled from TikTok's Research API.

Appendix Figure A37: *Emotions expressed in political videos by video length*

Notes: This figure replicates Figure 9 Panel (c) but plots the share of political videos classified as expressing each of the relevant emotions. A video can be classified as expressing more than one emotion.

Appendix Figure A38: *Emotions expressed by partisan versus nonpartisan political videos*

Notes: This figure plots the gap in codings of each emotion's prevalence between political videos coded as partisan versus nonpartisan.

G Comparing TikTok to TV

G.1 TV consumption

Table A13 estimates what percentage of TV viewing goes to (i) news, (ii) the subset of news that is about politics or political issues according to the definition our classification schema uses, and (iii) the subset of political news minutes that are partisan, again according to the definition our schema uses. Data are sourced as follows, mostly from Noy and Rao (2026).

1. Ratings are taken from Nielsen AdIntel C3 for 2019 and news programs are ABC, CBS, NBC, CNN, Fox News, and MSNBC.
2. We sample news minutes on those programs in 2026 from the TV archive and classify each minute using an LLM prompt analogous to the one used to classify TikTok videos. This allows us to detect whether a minute is political and, if so, whether it expresses a clear partisan perspective. As with our TikTok data, we drop ad minutes and compute measures as shares of non-ad minutes.
3. The "Linear TV" column shows our estimates as percentages of cable and broadcast viewing minutes. "All TV" adds streaming, which made up about 20% of TV time in 2019 according to Nielsen's Total Audience Report. We assume streaming contains no political news.

Appendix Table A13: *News and political news as shares of TV viewing, and the partisan share of political news*

	Linear TV	All TV
News	14.4%	11.7%
Political news	10.3%	8.3%
Partisan (% of political news)	21.9%	21.9%

G.2 Political TikToks posted by users versus news organizations

Posts by news organizations make up 27% of the political videos in viewers' TikTok feeds. Of these, only 14% are partisan, compared to 67% of user-generated political content. Appendix Figure A39 Panel (a) shows this is because TikTok viewers prefer nonpartisan news organizations. The top outlet for American political news among both Democrats and Republicans in our sample is the Daily Mail, a British tabloid; the next slots are occupied by CBS, NBC, and CNN. Panel (b) shows that the clips news organizations post on TikTok are *less* partisan than their typical broadcasting, and, among the clips they post, the nonpartisan ones receive more views.

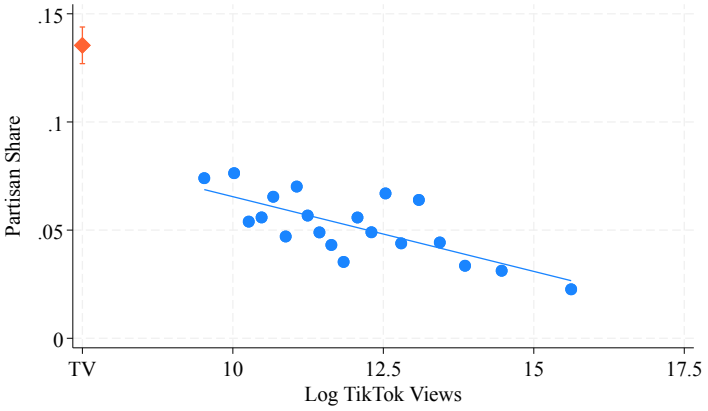

Panel (d) of Appendix Figure A39 shows that early in a TikTok session, a higher proportion of the political videos viewers see are from news organizations; as viewers scroll and the scarcity from Figure 6 Panel (b) kicks in, TikTok increasingly relies on user-generated political content. Overall, this pattern of results suggests the partisanship of consumed political content may be partly driven by the supply side of amateur production.

Appendix Figure A39: *Viewers prefer nonpartisan news outlets on TikTok*

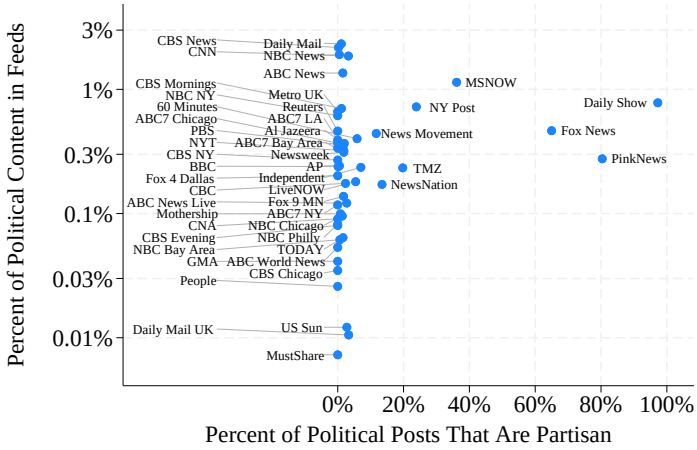

(a) *Top political news outlets in Democrats' and Republicans' feeds*

Democrats	Republicans
1. Daily Mail	1. Daily Mail
2. CBS News	2. CBS News
3. CNN	3. NBC News
4. NBC News	4. Fox News
5. ABC News	5. ABC News
6. MSNOW	6. CNN
7. The Daily Show	7. New York Post
8. CBS Mornings	8. CBS Mornings
9. NBC New York	9. Metro UK
10. New York Post	10. Reuters

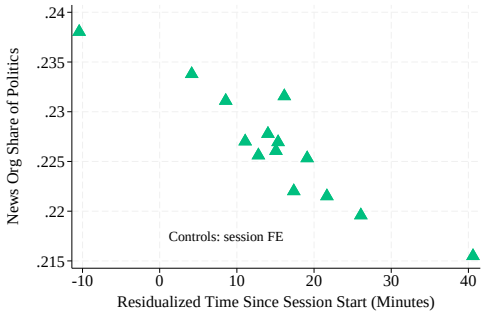

(b) *News organizations' more partisan videos receive fewer views on TikTok*

(c) *Partisanship of news outlets by presence in feeds*

(d) *News organizations' share of political videos falls as a session goes on*

Notes: These panels are constructed from our data on participants' viewership histories plus TV data from the TV News Archive (Noy and Rao, 2026). Panel (a) lists the ten news outlets responsible for the largest numbers of videos about American politics in participants' feeds, separately for participants who self-identify as Democrats versus Republicans. The blue dots in Panel (b) use political news videos posted on TikTok by ABC, CBS, CNN, NBC, and Fox News, weighting each outlet equally. The panel shows a binned scatterplot of whether the video was partisan against its view count on TikTok. The orange diamond instead plots the percent of 60-second political news segments *broadcast* on these channels in 2026 that we code as partisan. Panel (c) plots the top 50 news outlets by frequency of appearance in participants' feeds, plotting this frequency on the y-axis and the percent of the outlet's political news posts in June and July of 2026 classified as partisan. Panel (d) replicates Panel (b) of Figure 6 but plots on the y-axis the share of political videos posted by news organizations.

H Viewership Experiment

H.1 Design details

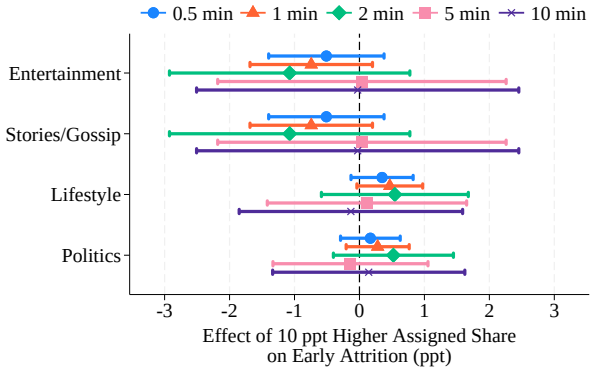

Appendix Figure A40: *Viewership experiment interface*

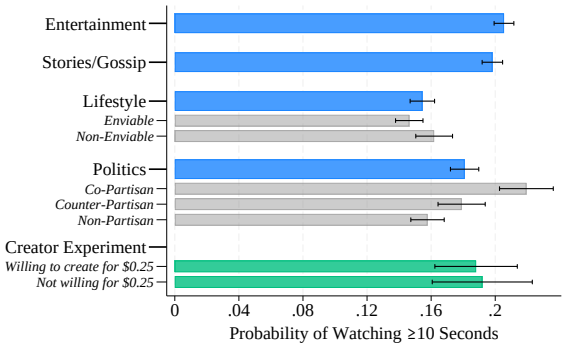

H.2 Additional exhibits

Appendix Figure A41: *Attrition is unrelated to feed composition, and including incomplete sessions does not change results*

(a) *Early attrition by randomized feed composition*

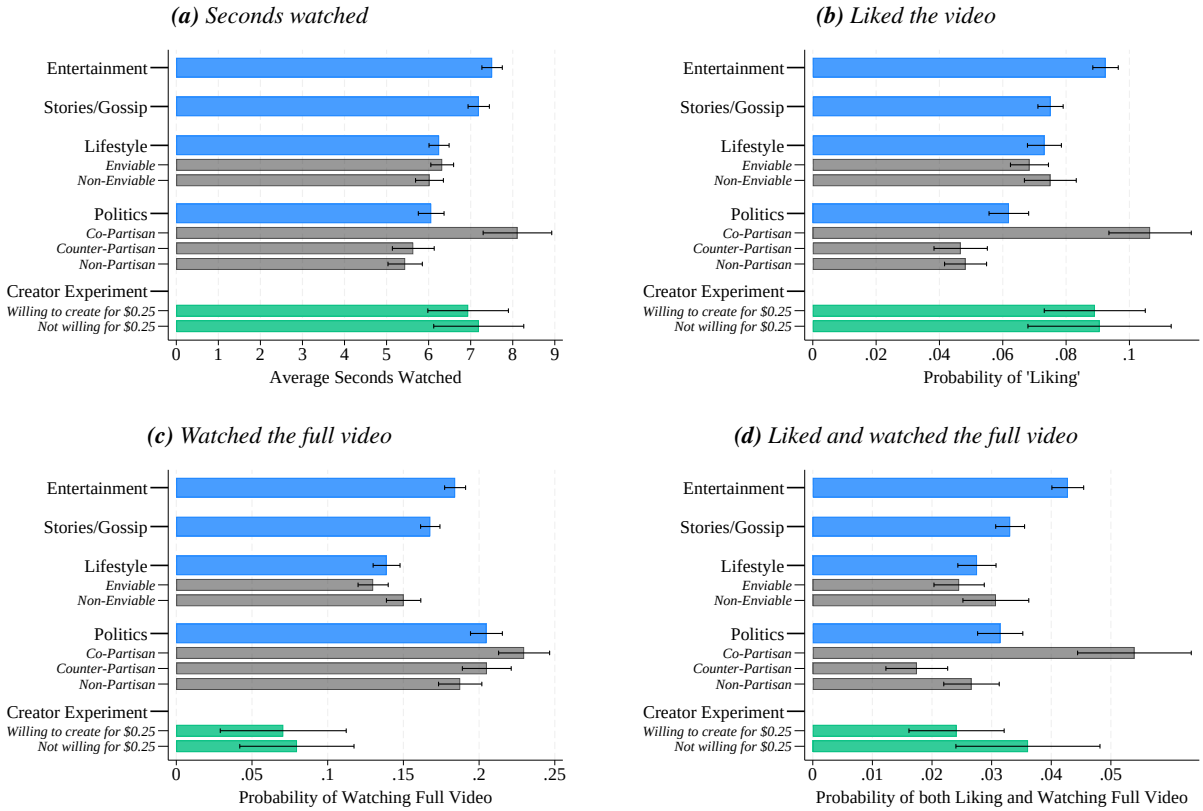

(b) *Probability of watching ≥ 10 seconds, including incomplete sessions*

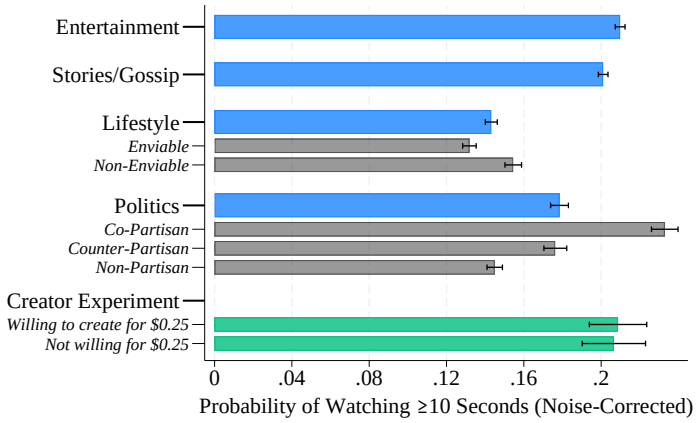

Notes: This figure plots data from our viewership experiment. Panel (a) plots regressions predicting attrition by 0.5, 1, 2, 5, or 10 minutes using the share of a participant's feed up to that point assigned to a given content type. Panel (b) replicates Figure 11 Panel (c) keeping incomplete sessions instead of dropping them.

Appendix Figure A42: *Engagement by content type: other pre-registered measures*

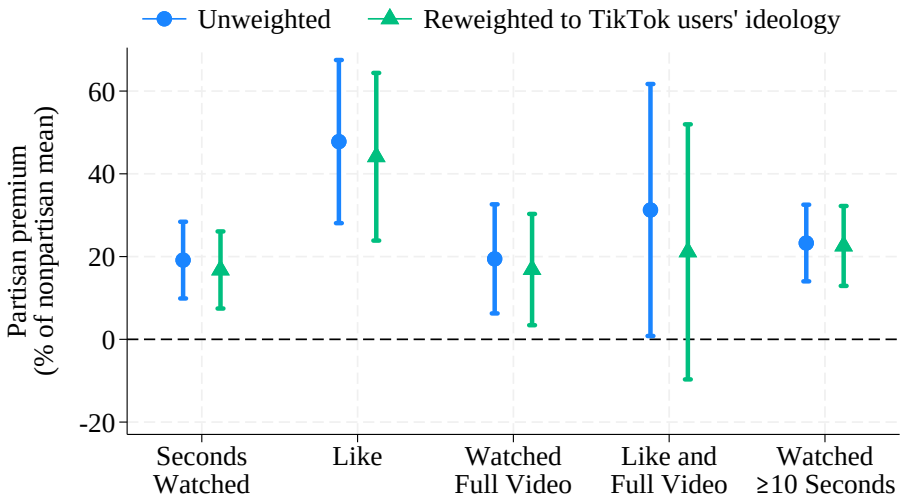

Notes: This figure replicates Figure 11 Panel (c) for each of our other pre-registered outcome variables: (a) seconds watched, (b) whether the participant liked the video, (c) whether they watched the full video, and (d) whether they both liked it and watched all of it. As in that figure we control for participant, video length decile, and sampling source fixed effects.

Appendix Figure A43: *Probability of watching ≥ 10 seconds by content type, correcting for behavioral noise*

Notes: This figure replicates Figure 11 Panel (c) after disattenuating estimates by purging behavioral noise with an empirical Bayes correction using the end-of-experiment module where we show participants two videos they saw earlier and ask which they prefer.

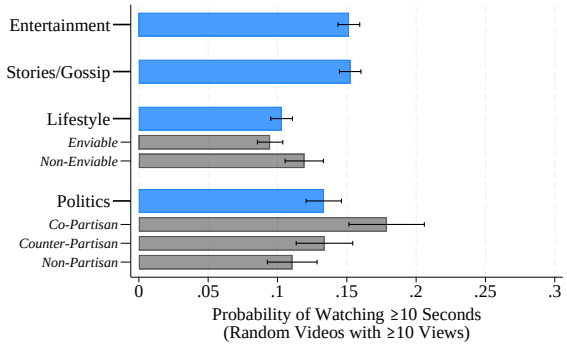

Appendix Figure A44: *The partisanship premium, reweighting participants to the ideology of young TikTok users*

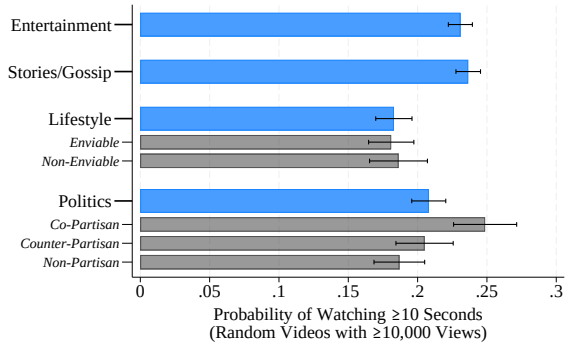

Notes: For each of our five pre-registered engagement outcomes, this figure plots the engagement difference between partisan and nonpartisan political videos using our main specification, either unweighted or weighting participants so they match the ideological distribution of 18-30 year old TikTok users from the American National Election Studies (Table A1).

Appendix Figure A45: *Probability of watching ≥ 10 seconds by content type, separately by the view-count floor used to sample random videos*

(a) *Random videos with at least 10 views*

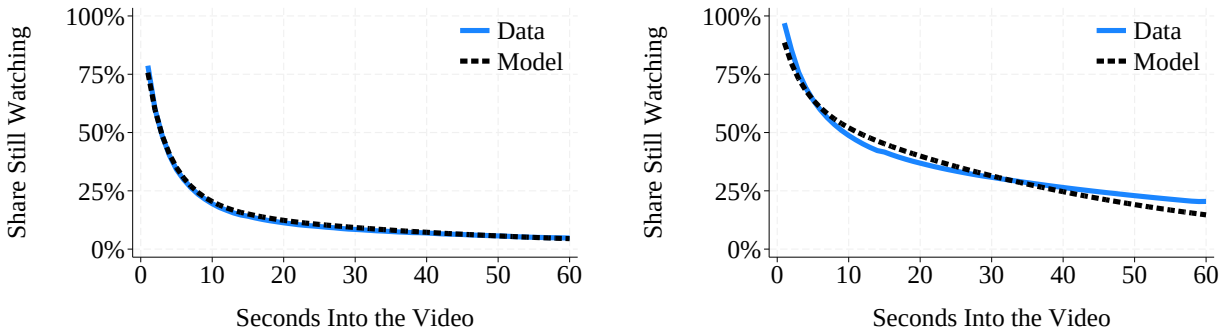

(b) *Random videos with at least 10,000 views*

Notes: This figure replicates Figure 11 Panel (c) separately for two groups of videos. When we randomly sample videos from TikTok's Research API we use either a 10-view or a 10,000-view floor. Panels show our main estimates on videos sampled in each case.

Appendix Figure A46: *Watch times in the data and in our model*

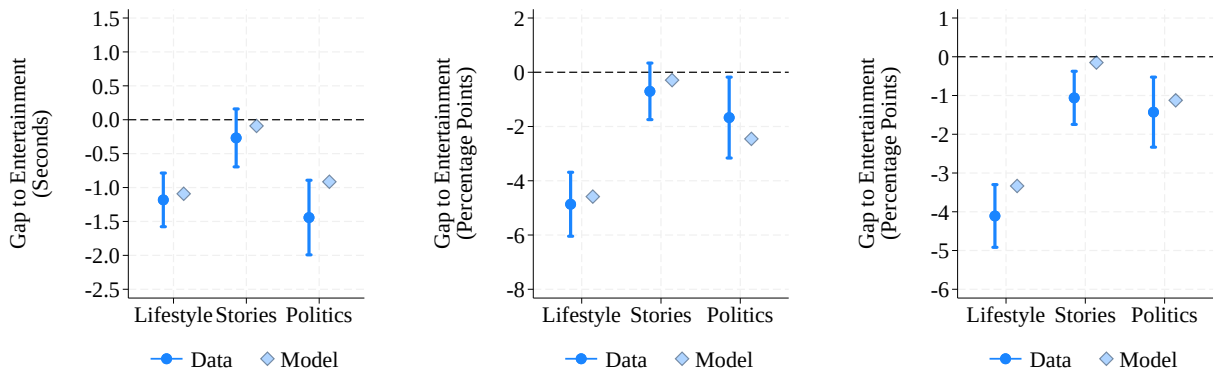

(a) *Viewership experiment* ***(b)*** *Participants' actual TikTok feeds*

Notes: The blue line in Panel (a) plots the share of views in which the viewer is still watching the video t seconds in (restricting to videos at least t seconds long) across all occurrences in our viewership experiment. The black dashed line shows the distribution simulated by our model. Panel (b) reproduces this in our observational viewership-history data, re-calibrating the reservation value of swiping to the next post to match the share of viewers watching videos for at least five seconds and assuming that each video in a person's actual feed is drawn from the model's utility distribution truncated above this reservation value.

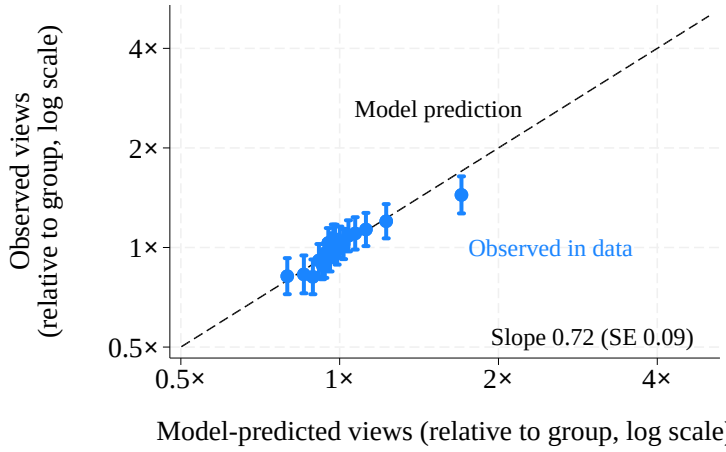

Appendix Figure A47: *Engagement by content type in the viewership experiment: data and model*

(a) *Seconds watched* ***(b)*** *Watched at least 10 seconds* ***(c)*** *Watched the full video*

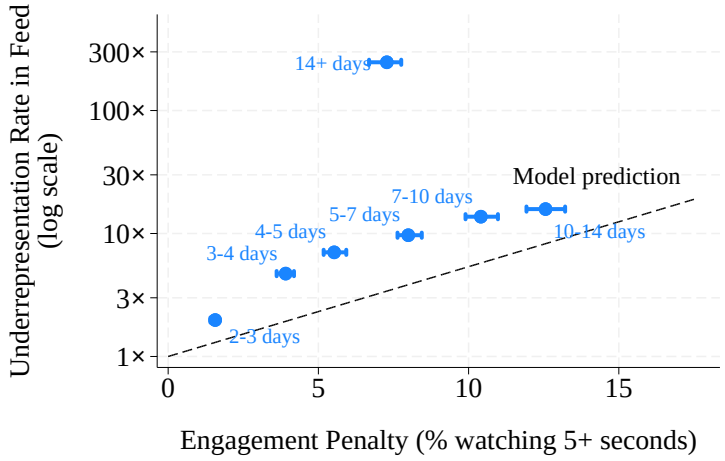

Notes: These figures plot coefficients from pre-registered regressions of engagement outcomes on dummies for content types, with fixed effects for participant, video length decile, and sampling source. Next to these coefficients, we display the analogous coefficients using viewership simulated from our model estimates.

Appendix Figure A48: *Predicted and actual TikTok views of the videos in our viewership experiment*

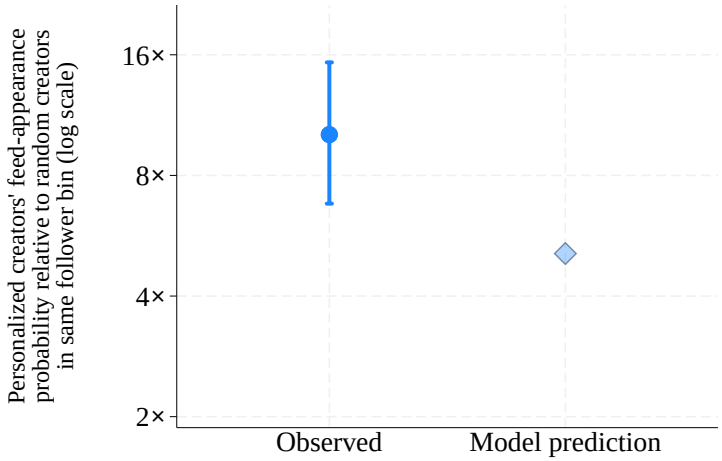

Notes: This figure plots the realized view counts on TikTok of the videos used in our viewership experiment against the view counts predicted by our model based on utility estimates from the engagement behavior of experimental participants. It plots this slope within groups (follower count × content type × sampling source). The black dashed line is the 45 degree line, reflecting perfect concordance between our model estimates and actual viewership.

Appendix Figure A49: *Stale videos' engagement and feed-appearance penalties: data and model*

Notes: This figure buckets posts in our viewership history by their "age" (the time between their posting and their appearance in a viewer's feed). On the x-axis it plots the average engagement penalty associated with a bucket relative to videos 1–2 days old, measured as the percent of viewers watching them for at least five seconds. On the y-axis it plots the feed appearance penalty of this bucket, meaning how much less common videos from this bucket are relative to videos 1–2 days old. The dashed line shows our model's prediction about the effects of a given decrease in the engagement measure on a video's probability of appearing in a viewer's feed.

Appendix Figure A50: *Feed appearances of videos by creators viewers regularly see: data and model*

Notes: This figure studies the subset of participants in our viewership experiment for whom we pipe in "personalized" videos recently posted by a creator who appeared at least 3 times in their TikTok viewership history. It plots how much more likely a random video from such a creator is to appear in their feed than a random video from another creator from our experiment in the same number-of-followers bin, based on comparing the historical overlap between their viewership histories, the posting rates of the personalized creators, and the production and consumption shares of creators in this follower bin. It also plots our model's prediction for this ratio.

Appendix Table A14: *Fit of different distributions to the upper tail of video views*

				Share of tail videos with ≥ v views (%)			
	Log-likelihood	ΔAIC	KS distance	v =10K	100K	1M	10M
Data				37.3	9.00	1.19	0.054
Lognormal	−277,183	0	0.018	37.7	7.94	1.45	0.230
Pareto	−277,216	63	0.012	36.6	8.32	1.89	0.429
Weibull	−277,427	486	0.051	41.1	7.45	0.729	0.031
Exponential	−317,840	81,312	0.548	89.8	26.3	0.000	0.000

Notes: This table compares the fit of different parametric distributions to the upper tail of view counts in our random sample of produced TikToks drawn from the Research API. Each distribution is fit by maximum likelihood. The first column reports the log-likelihood, the second the difference in AIC from the best-fitting distribution (the log-normal), and the third the largest gap between the fitted distribution and empirical distribution.

I Creator Experiment Details

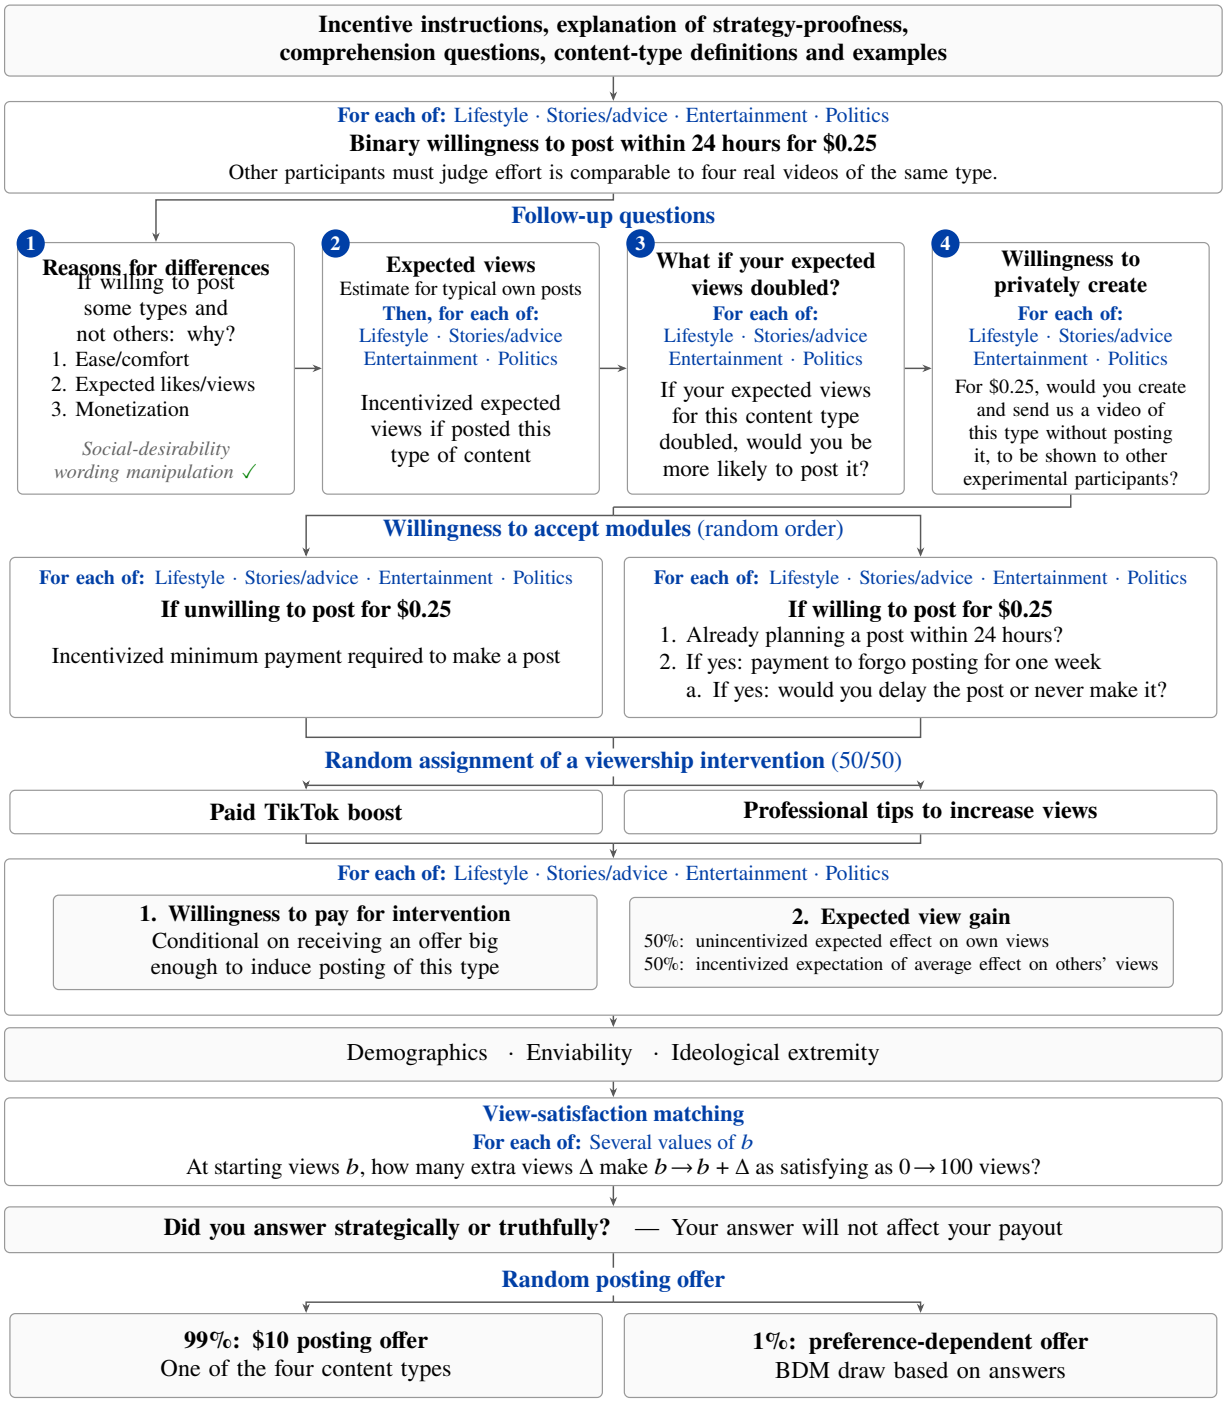

I.1 Design details

Our creator experiment was conducted in August 2026 and our reduced-form analyses were preregistered on the Open Science Framework at `https://osf.io/24tcz`. We invited participants who had completed our user survey and logged in with a public TikTok account with at least one post, and allowed new participants to enter the survey by logging in with a public TikTok account with at least one post. 1,115 creators entered the experiment after logging in and 979 completed it. As preregistered, we exclude participants who indicate at the end that they answered strategically rather than truthfully (29 participants) or reported any monetary value exceeding $1,000 (36 further participants). We scrape participants' TikTok accounts and recover posting histories for 770 of them.

Figure A51 displays the survey flow and the full survey can be clicked through at `https://demo.mitsocialmediastudy.com/`. Completing the survey takes 14 minutes on average.

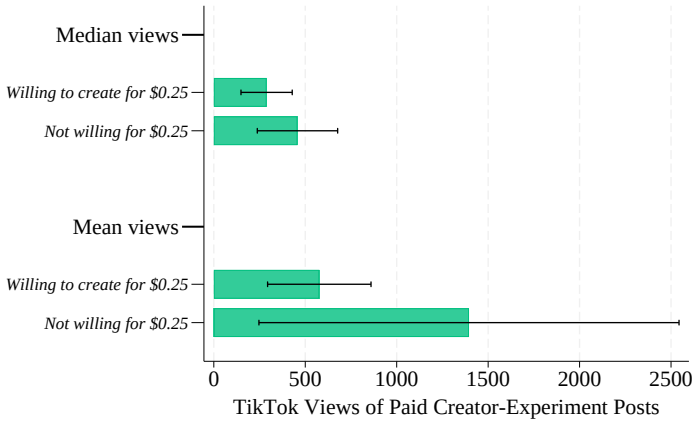

At the end of the survey each creator is extended a randomized offer. With 1% probability this offer is drawn from a BDM mechanism based on their willingness to post answers and with 99% probability it is a $10 offer to post one of our four content types, chosen at random. We start the probabilities of each type at 25% each and then, as data collection continues, adjust them to achieve a balanced sample of created videos of each type given creators' offer acceptance rates across types.

I.2 Additional exhibits

Appendix Figure A52: *TikTok views of paid creator-experiment posts, by creators' willingness to post for $0.25*

Appendix Figure A53: *Creator payoff parameter estimates: creators with at least 1,000 followers*

Parameter	Estimate	SE
Mean taste μ_k, % relative to entertainment		
Lifestyle	13.5	(3.2)
Stories	−6.5	(4.3)
Mean taste μ_k, % relative to nonpartisan politics		
Partisan politics	6.0	(25.8)
Value of views β	1.44	(0.25)
Curvature ρ	0.33	(0.005)
Expected views, creators willing to post only some types		
Types willing to post for $0.25	1111	(117)
Types not willing to post for $0.25	822	(115)
Expected views, % relative to entertainment		
Lifestyle	−37.1	(4.7)
Stories	−33.0	(5.2)
Expected views, % relative to nonpartisan politics		
Partisan politics	106.8	(55.7)
For the median planned post		
Total utility from post	$7.14	(1.85)
Utility from viewership	$12.65	(2.25)
Utility from first 100 views	$6.63	(1.13)

Notes: This figure replicates Panel (b) of Figure 12, estimated only on creators in our experiment with at least 1,000 followers.

Appendix Table A15: *Creator results are robust to the valuations of creators already planning to post*

Specification	Creators	Mean taste, % cheaper		Oaxaca supply contribution (pp)		Supply-equalized counterfactual	
		Lifestyle vs. ent.	Partisan vs. nonpart.	Lifestyle − ent.	Partisan − nonpart.	Lifestyle share (%)	Partisan share (%)
Main estimates	770	8.8	35.3	22.8	14.8	19.4	32.2
		(1.5)	(8.5)				
Creators who would forgo rather than delay	486	9.4	37.7	23.6	17.4	18.2	42.5
		(2.5)	(11.1)				
Planning-branch payments ×1.1	770	8.9	34.9	22.5	14.8	19.4	32.6
		(1.5)	(8.3)				
Planning-branch payments ×1.2	770	8.9	34.4	22.2	14.9	19.5	32.8
		(1.5)	(8.2)				
Planning-branch payments ×1.5	770	8.9	33.1	21.5	15.0	19.5	33.3
		(1.4)	(7.7)				
Planning-branch payments ×2	770	9.0	31.3	20.6	15.0	19.6	33.5
		(1.4)	(7.0)				
Planning-branch payments ×3	770	9.0	28.6	19.5	14.9	19.7	33.6
		(1.4)	(6.0)				

Notes: This table plots robustness of our creator-experiment results to the treatment of the "willingness to pay to keep posting" question branch where creators who were already planning to post a given type of content tell us how much we would need to pay them not to post it for a week. Most creators who respond to this question answer a followup by saying this would lead them to postpone making the post rather than not make it at all, so treating their WTP divided by their expected number of posts as their per-post valuation may underestimate their true valuation. Here we simply test sensitivity of our results to this kind of underestimation by multiplying responses in this branch by increasing numbers.

Appendix Table A16: *Creator results are robust to how we elicit the expected effects of the boost*

Boost question	β	Mean taste, % cheaper		Oaxaca supply contribution (pp)		Supply-equalized counterfactual	
		Lifestyle vs. ent.	Partisan vs. nonpart.	Lifestyle − ent.	Partisan − nonpart.	Lifestyle share (%)	Partisan share (%)
Both groups (main)	1.20	8.8	35.3	22.8	14.8	19.4	32.2
	(0.09)	(1.5)	(8.5)				
Own views (unincentivized)	1.24	8.8	35.2	23.0	14.7	19.4	32.1
	(0.14)	(1.5)	(8.5)				
Others' views (incentivized)	1.16	8.9	35.4	22.5	14.9	19.4	32.5
	(0.11)	(1.5)	(8.5)				

Notes: This table shows robustness of our creator-experiment results to whether participants' expected effects of the intervention we offer on their viewership are given in response to an unincentivized question about its expected effects on their own viewership or an incentivized question about its expected average effects on other participants' viewership.

I.3 Social desirability

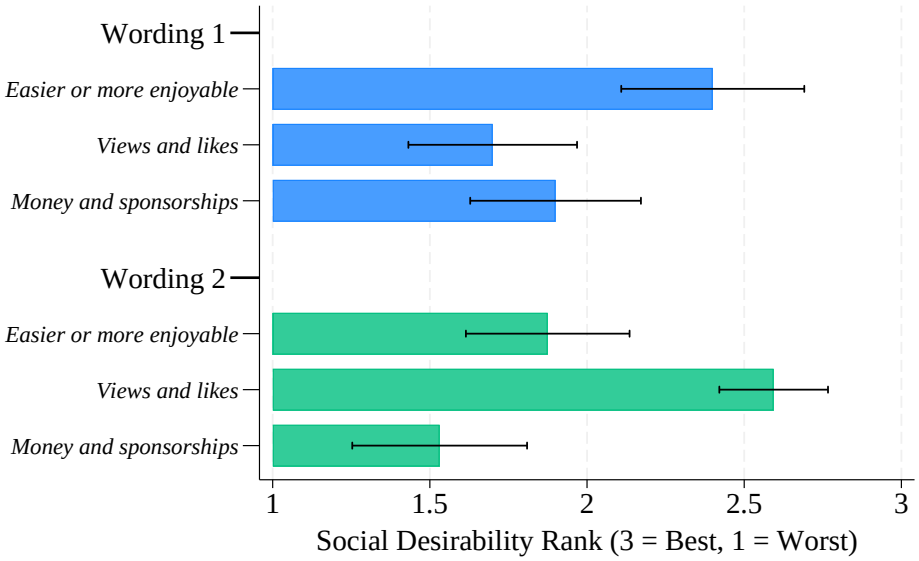

Panel (e) of Figure 12 asks creators who accepted the $0.25 offer for some content types but not others why they did so. The question first reminds them of their choices and then asks: "What is the main reason you would accept the $0.25 offer for [the first group of content types], but not for [the second group]?" It offers

four answer options and we randomize the wording of one of them to flip its perceived social desirability.

1. Creating posts of the former types would be easier or more enjoyable, or you would be more comfortable posting them.
2. *Original wording:* You care about how popular your post is (how many views or likes you would get), and you expect you would get more views and likes from posts of the former types.
   Flipped wording: You want to create content that reaches and engages people. You expect posts of the former types would receive more views and likes.
3. You think posts of the former types would create more opportunities to earn money, attract sponsorships, or build an audience you could monetize.
4. You were already planning to post the former types of content, but were not planning to post the latter types.

To verify that we flip social desirability successfully we run a supplementary survey of 62 respondents recruited via Prolific. Each respondent sees one of the two wordings and ranks the first three options from the one where giving it as the main reason makes a creator look best in other people's eyes to the one where it makes a creator look worst. Figure A54 shows results.

Appendix Figure A54: *Perceived social desirability of the creator experiment's stated reasons*

J Emotion-Sampling Details and Results

J.1 Design details

This section describes the features and technical implementation of our emotion-sampling app, and reports the results summarized in Section 5.

Recruitment. Appendix C summarizes the full details of recruitment and gives descriptive statistics on our sample and attrition. Briefly, we recruit 383 Americans aged 18-30 from Prolific who download our iPhone app, use it for a week, and then at the end of the week submit their viewership histories on TikTok, Instagram, and YouTube.

Onboarding. Upon first opening the app, users complete an onboarding flow in which they enter their registration code, consent to participate in the study, select wake-up and sleep times, indicate the three hours of the day in which they most frequently use social media, set up and activate monitoring of the relevant social media apps, read descriptions of the study procedures and their incentives, and finally complete a comprehension quiz.

Detecting social media usage. Users of our app are asked to enable iOS's Family Controls permissions and select monitoring of Instagram, YouTube, and TikTok. This allows our app to run a background monitor that tracks usage of these three social media apps. The monitor works on a refreshing cycle of 24 hours and, within each 24-hour cycle, records a new event whenever the user's usage of a given app crosses a threshold in a series of 4-minute increments between 0 and 240 minutes. (So, an event is recorded when the user crosses 4 minutes of usage, another at 8 minutes, another at 12, and so on, and these thresholds reset every 24 hours.) We separately run two monitors, one that pools Instagram and YouTube usage and another that just tracks TikTok usage. (We do this rather than running three monitors because iOS limits the number of threshold events that can be simultaneously registered.)

While iOS allows the usage monitors to run passively in the background, it does not permit our app (or any app) to be continuously active in a way that would let us automatically fire notifications when usage events are recorded by the monitors. Instead, we need the user to interact with the app in some way in order to foreground it sufficiently to let us check for recent usage and decide whether to schedule imminent notifications. (To the best of our knowledge, Android used to allow continuously active background monitoring but no longer does.)

Our solution to this problem is to blanket the user's day with quasi-randomly timed notifications, with particularly high density during periods of the day when social media usage is most common. When the user responds to a notification (either by tapping it and entering our app, or by press-holding and responding via the dropdown menu — a "notification action"), this foregrounds the app; we are then able to query the social media monitor and, if we observe a social media usage event within the past 10 minutes, we schedule additional ("followup") notifications over the next 12 minutes. Responses to *these* notifications then once again trigger a check for social media usage, allowing us to chain notifications while users are using social media.

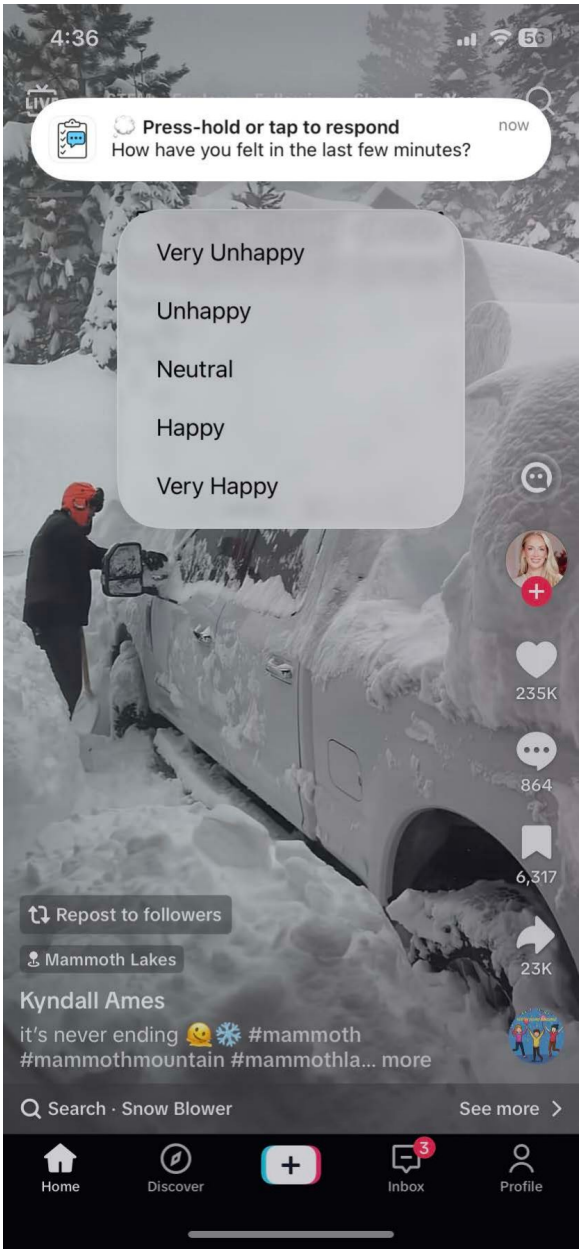

Creating notification schedules. iOS limits the number of notifications that an app can have scheduled at a given time. We therefore create notification schedules in 2-day blocks. The first block is created when the user completes onboarding. At the end of each second day, participants are delivered a high-priority "diary" notification; tapping this notification generates a notification schedule for the next 2 days and launches an AI-conducted interview that asks about the participant's emotions over the last 2 days. If the user does not tap the diary notification, backup diary notifications are delivered over the course of the next day to ensure continuation of the schedule.

Notification schedules are generated quasi-randomly according to the following rules:

- The three hours of the day that the respondent selected during Onboarding as the hours during which they most frequently use social media each receive three scheduled notifications with 100% probability. One is randomly scheduled within the first 5-15 minutes of the hour (with a uniform distribution in that window), one in 25-35, and one in 45-55.
- Non-social-media hours between 6pm and the user's indicated sleep time each receive two notifications with 100% probability. These are placed randomly within minutes 5-28 and 33-55.
- Non-social-media hours before 6pm receive a single notification with 10% probability, randomly and uniformly distributed between minutes 5 and 55.

Notification actions, content extensions, and notification pairing. To ensure that notifications are minimally intrusive, they allow participants to respond by press-holding the notification and giving a response in the dropdown menu that appears. This does not require the user to leave their current app, allowing (for example) a user scrolling through TikTok to quickly respond to a notification without interrupting their scrolling (see Figure A55).

Appendix Figure A55: *Emotion-sampling app interface*

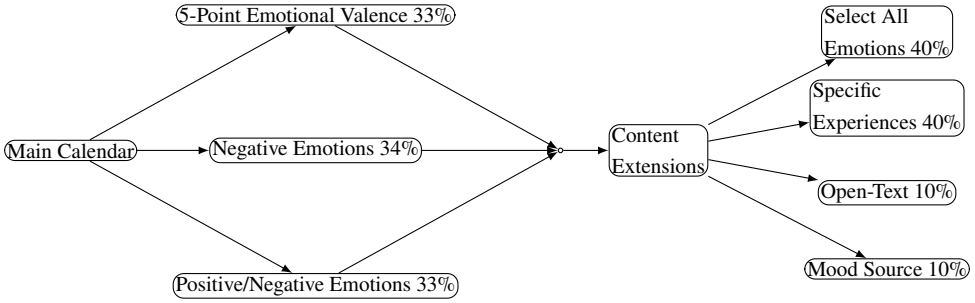

iOS allows both notifications that use *notification actions* and notifications that use *notification content extensions*. Both types allow press-hold dropdown menus. Notification action questions restrict us to a fixed list of answer options and a fixed order for those options, and only allow the user to select one option. However, responses to notification action questions allow us to foreground the app sufficiently to run the processes that check for recent social media usage and schedule background notifications. Notification content extensions allow us to use "select all that apply" questions and randomize the answer options and the order in which they are presented, but do not allow us to foreground the app.

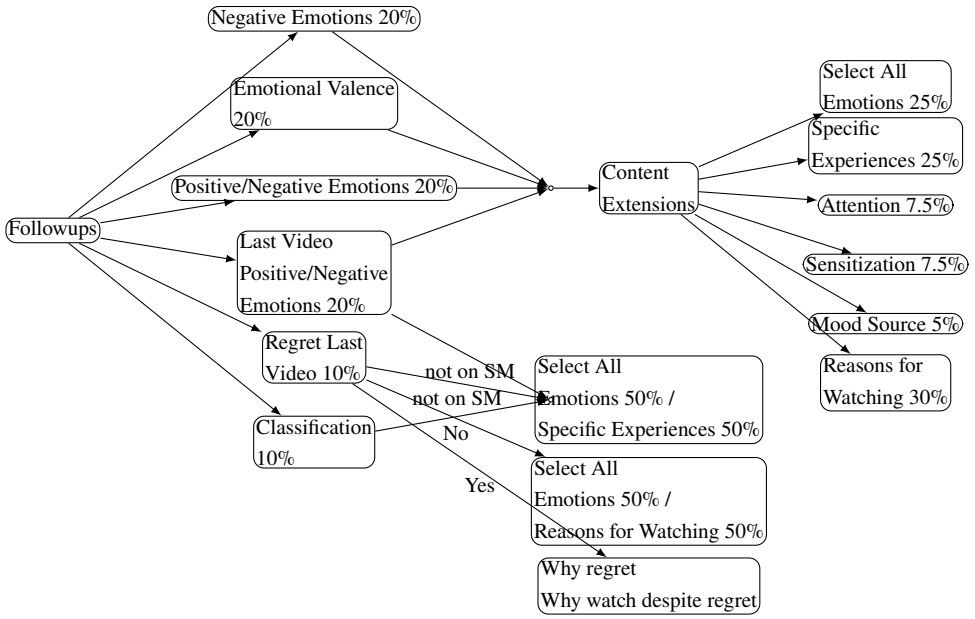

To get the best of both worlds, we pair notifications: we schedule notification-action questions, and a response to a notification-action question immediately triggers a complementary content-extension question.

The types and probability distributions of notifications are listed below.

Appendix Figure A56: *Types and probabilities of notifications on the main calendar*

Appendix Figure A57: *Types and probabilities of followup notifications triggered by detected social media usage*

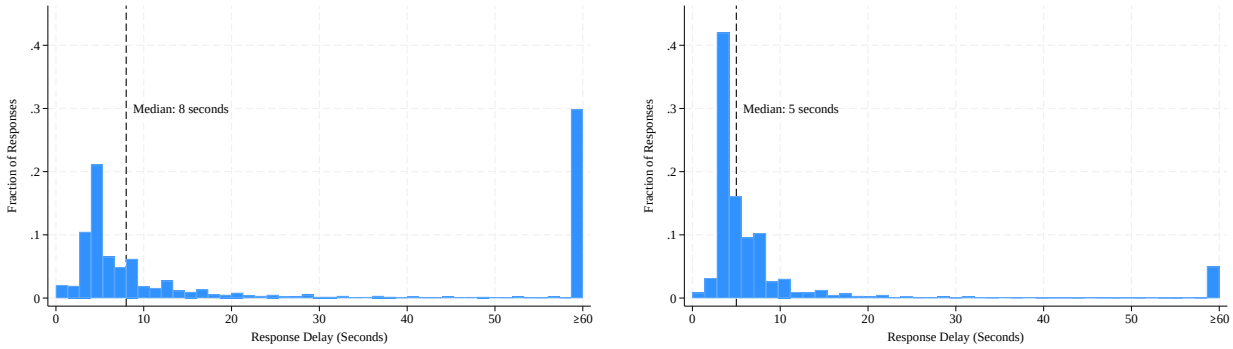

Incentives. Participants' final payments range between $15 and $40 and depend on two metrics we track and display on a dashboard within the app: the number of notifications responded to while on social media, and response speed to notifications delivered while on social media. Participants are told they do not need to worry about responding to notifications delivered while they are not using their phones or not on social media. These incentives result in a response rate of 37% for notifications delivered while the participant is *off* social media and 99% for notifications delivered while the participant is *on* social media (we can observe social media usage perfectly using the participant's viewership histories). Figure A58 plots the median response delay (time between notification delivery and response receipt); the median response delay to notifications delivered during social media use is 5 seconds. We examine response delays extensively in our discussion of threats to identification. The rapid responses and very high response rates we observe during our periods of interest are consistent with the "typically quite small [...] delay in response[s]" observed in experience-sampling studies surveyed by Csikszentmihalyi and Larson (1987).

Figure A59 plots participants' daily TikTok use before and after they start using the app. It shows that

TikTok usage slightly rises in volume during the week where participants are incentivized to respond to notifications. Our observational analysis in the main body of the paper mostly uses data from the 6 months of viewership history preceding participants' engagement with our app and hence will not be affected by this.

Appendix Figure A58: *Response delays to emotion notifications*

(a) *Notifications delivered while off social media* ***(b)*** *Notifications delivered while on social media*

Notes: This figure plots distributions of notification response delays, defined as the number of seconds between notification delivery and notification response for notifications that are responded to. Panel (a) plots the distribution for notifications delivered while the recipient is not on social media, while Panel (b) plots notifications delivered while the recipient is on social media. (Social media usage is measured through viewership histories.)

In part for the technical reasons described above relating to notification actions versus content extensions, each notification bundles a primary emotion question with a secondary question triggered immediately after a response to the primary. We randomize primary emotion questions between three wordings, both to demonstrate robustness and because participants in pilots complained about the monotony of repeatedly responding to the same question. One wording asks for the participant's emotional valence on a 1-5 point scale; the second asks if the participant has recently experienced any positive and any negative emotions; and the third asks if the respondent has recently experienced any of a list of negative emotions constructed from open-ended pilot surveys (anger, anxiety, depression, hollowness, inadequacy, or self-consciousness). All questions ask about feelings over the past few minutes, consistent with our strategy of sampling emotions every few minutes during social media usage sessions and examining within-session variation in emotions. Secondary emotion questions follow a "select all of the above" format and ask about specific emotions experienced over the past few minutes, sources of the user's mood over the last few minutes, or (if the notification was triggered by social media usage detection) questions relating to the recent posts viewed by the user.

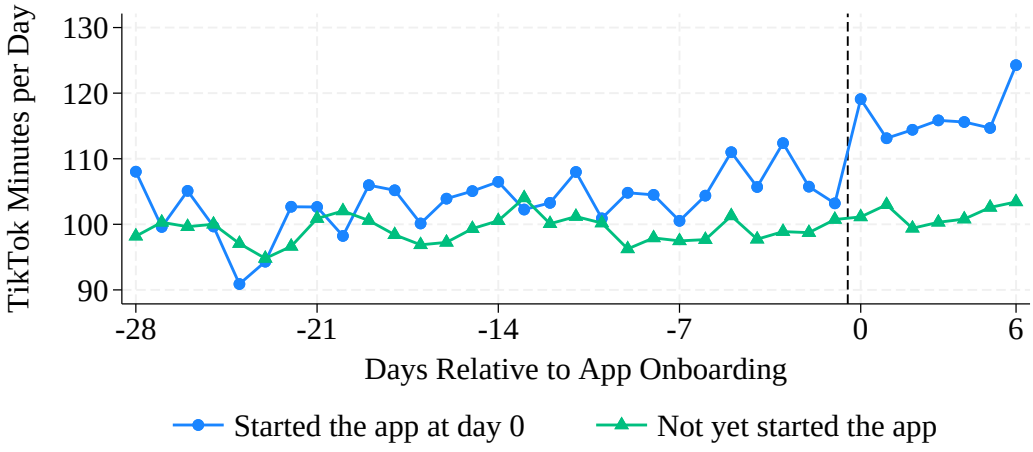

AI interviews. The app occasionally delivers AI-conducted interviews to participants: when a user is detected to have been on social media for an extended period of time,[36] the app sends a notification that, when tapped, prompts the user to engage in a short conversation with an AI. The AI opens by asking whether any pieces of content the user has seen on social media over the last few minutes triggered negative emotions; if so, it asks about the type of content and the nature of the emotions; finally, it asks why the user continued to view the content despite the fact that it triggered negative emotions, and whether the video was selling or

[36]The precise condition is that at least 4 notifications have been triggered by social media usage detection in the past 120 minutes; in this case, each new notification scheduled by usage detection has a 30% chance of being an interview, up to one interview per day.

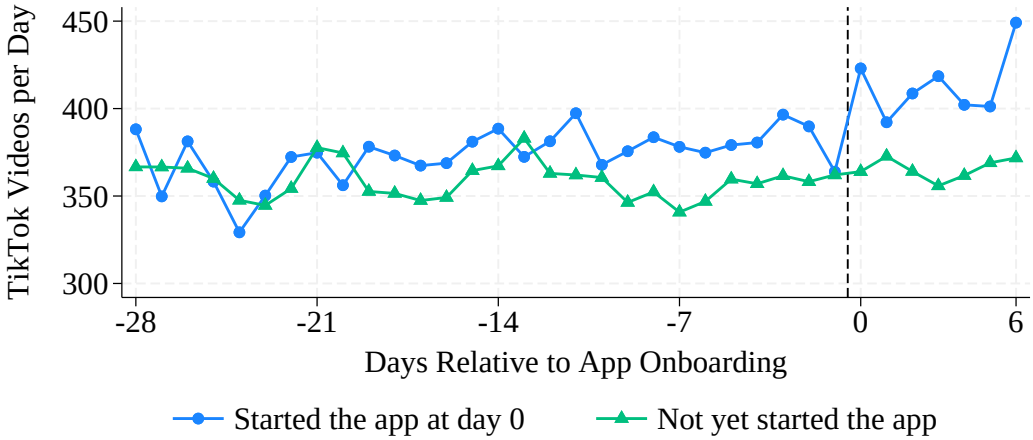

recommending a product. The system prompt is carefully designed to ensure that the AI never leads users towards any particular answer.

Appendix Figure A59: *Daily TikTok use before and during the emotion-sampling week*

(a) *Minutes per day*

(b) *Videos per day*

Notes: Blue circles show average daily TikTok use among participants who donate their viewership histories, before versus after they enter our experiment by downloading our emotion-sampling app. It stacks users who have versus have not yet started the app.

Emotion measurement. We embrace the point that people's utility functions are multi-dimensional (Bernheim, 2009; Benjamin et al., 2014). Someone may enjoy watching a movie even though (or *because*) it is sad, or may find a video simultaneously interesting, amusing, and upsetting. This connects naturally to our conceptual framework's emphasis on the way that pieces of content are high-dimensional bundles of features. Each feature may provoke a different dimension of subjective response in the viewer. We therefore focus on measuring a range of *emotions* as well as general emotional valence, and do not interpret our results as reflecting cardinal measures of viewer utility. In this sense we do not view ourselves as eliciting measures of overall subjective wellbeing.

There are also several other ways that our measurement technique sidesteps common concerns in the literature on elicitation of subjective wellbeing. First, the primary concern in this literature is that using

subjective wellbeing data to draw inferences about cross-individual or cross-group differences in cardinal utility requires very strong assumptions (Bond and Lang, 2019). We examine only *within*-person variation in emotions, relating such variation to within-person variation in content viewed on social media. We also do not interpret these emotions as necessarily reflecting cardinal utility, as explained above.

Another major concern relates to the interpretation of life-satisfaction questions commonly included in national surveys. Responses to such questions can be biased by imperfections in memory such as the peak-end rule (Kahneman et al., 1993; Kahneman and Thaler, 2006), or can turn on differences in respondents' interpretations of the time horizon over which the question is quantifying (Benjamin et al., 2024). These considerations led Kahneman and Krueger (2006) and Krueger and Schkade (2008) to label high-frequency sampling of contemporaneous emotions—"experience-sampling" of the kind we perform—the gold standard of subjective wellbeing measurement.[37] We follow best practices in the experience-sampling literature described by Csikszentmihalyi and Larson (1987) and Stone and Shiffman (1994): timing emotion assessments close to relevant stimuli, collecting large numbers of observations per person, pinging participants in their typical daily environments, quasi-randomly varying question timing within fixed blocks, collecting brief, minimally onerous measurements, and measuring multiple dimensions of emotion and mood.

As preregistered, we aggregate the various randomized questions we ask about emotions into a single summary measure through the following steps. We assign each question type to an ordinal scale from least to most positive (for example, our questions that ask about the presence of positive or negative emotions get coded to -1 if the respondent indicates negative but not positive emotions; 0 if the respondent indicates both or neither; and 1 if the respondent indicates positive but not negative emotions). We then z-score responses within each question category and aggregate primary and contemporaneous secondary emotion questions into a single measure by averaging the z-scores.

J.2 Results

Baseline specification. Our baseline estimates of the effects of different content types on emotional valence come from the following parsimonious regression specification:

$$y_{it} = \beta x_{it} + \gamma_{s(it)} + \varepsilon_{it} \tag{19}$$

Here an observation is an emotion response received from individual i at time t while using TikTok. (As preregistered, we restrict to TikTok because it is the only platform where we can be confident that the user is on an infinite-scroll feed almost all of the time.) x_{it} is a vector of characteristics of the video the individual was viewing at the time they responded to the emotion notification, and $\gamma_{s(it)}$ are fixed effects for the social media usage session. A "session" is a contiguous block of time spent on social media by a particular user, identified from users' viewership histories; in our sample, the average session containing at least one emotion response contains 2.7 responses.

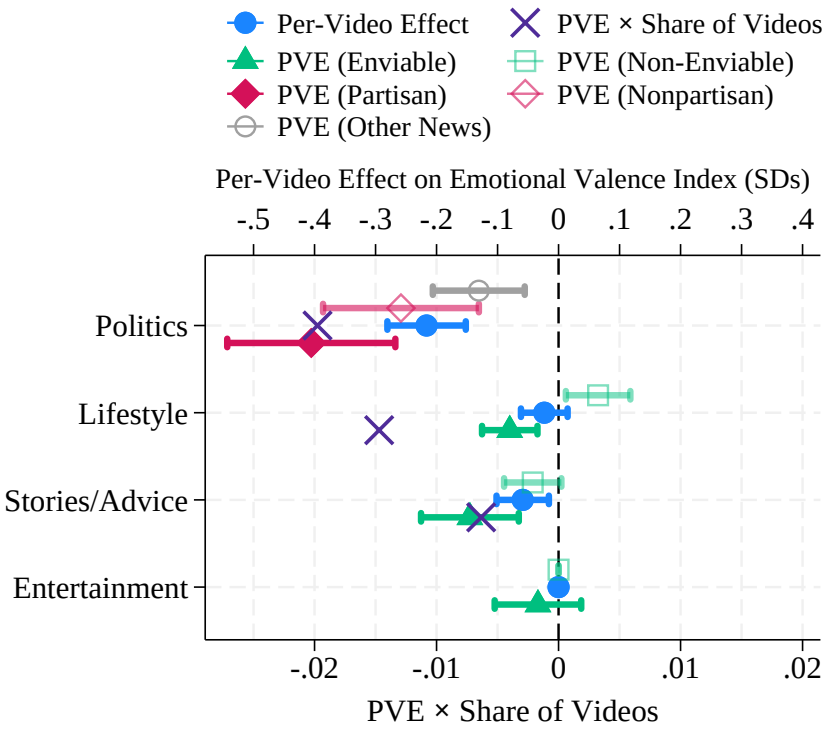

[37] Conceptually, such measurement techniques follow from the Benthamite tradition of viewing utility as the integral of flow hedonic experiences over time.

Baseline results. Figure A60 plots blue coefficients estimated from Equation (19) where the content vector x_{it} is our four main content quadrants (lifestyle, stories, and politics, with entertainment as the omitted category). The green coefficients split non-politics content types according to *enviability*, a coding of whether the focal person in the video is substantially more attractive, wealthy, or otherwise desirable than their typical peer. Figure A61 shows this is a coding that mainly loads on lifestyle videos. The red coefficients split politics videos according to whether they are coded as partisan or nonpartisan.

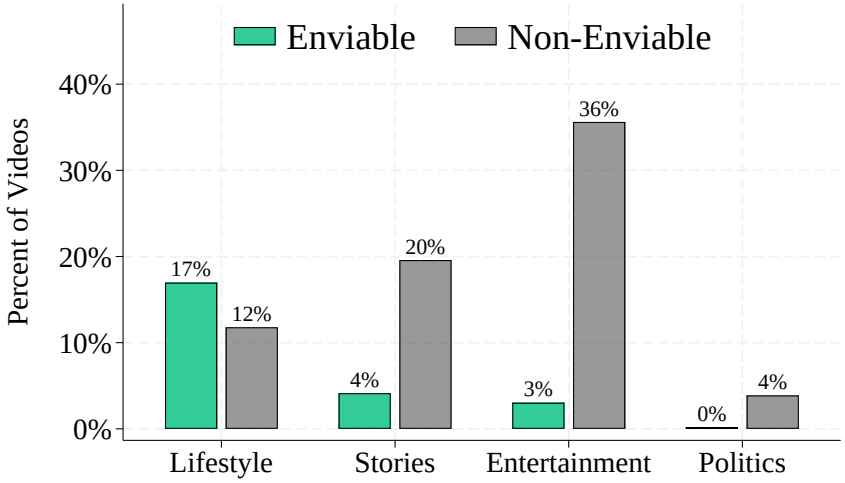

The coefficients show that, within usage sessions, emotional valence responses received while users are watching an enviable lifestyle video are 0.08 SDs lower, controlling for the other features of the video represented in the coefficient plot. Responses received while watching videos about politics are 0.22 SDs lower, and responses received while watching stories or advice videos prominently featuring an enviable focal person are 0.15 SDs lower. Among political videos, partisan videos lower emotional valence by 0.15 SDs more than nonpartisan videos, though this difference is not statistically significant ($p = 0.11$).

These "per-video" coefficients do not account for the fact that enviable lifestyle content is substantially more common than content containing political news; when we rescale these coefficients by the prevalence of the underlying content type (purple crosses), enviable lifestyle content becomes comparably important to political content in driving negative emotional valence.

Appendix Figure A60: *Emotion-sampling: what content types reduce contemporaneous emotional valence?*

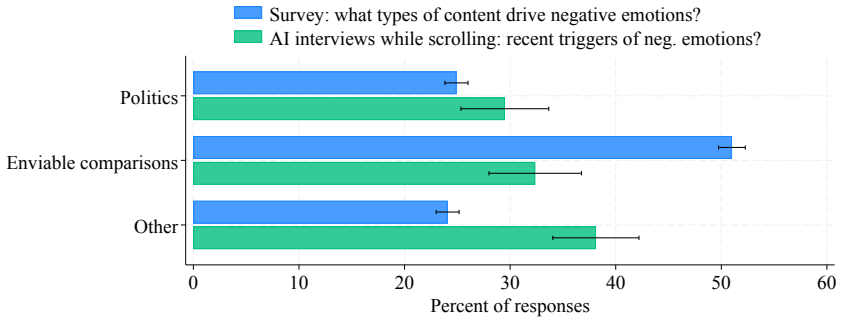

Appendix Figure A61: *Enviability by content type on TikTok*

Notes: This figure replicates Figure 7 Panel (a) but splits each content type into videos coded as enviable vs. non-enviable. To remain consistent with the figure it uses a narrower definition of politics than Figure A60 (all videos flagged as explicitly and primarily political, rather than all videos containing some news).

Corroborating evidence. Figure A62 shows that these estimates line up with two sources of self-reports. Across categories of content, the categories that have the largest estimated negative effects on emotional valence in our regressions are also the ones most frequently mentioned in responses to (i) our open-ended screening survey question that asks what types of content on social media most often trigger negative emotions in users, and (ii) AI interviews we deliver during social media usage that ask whether any content the user saw over the last few minutes triggered negative emotions.

Appendix Figure A62: *Open-ended surveys and interviews: what content types drive negative emotions on social media?*

J.3 Threats to identification

Ideally, we would like to interpret the associations documented above as causal, and say, for example, that exogenously encountering an enviable lifestyle video reduces emotional valence by 0.08 SDs. Our restriction to *within*-session variation in content exposure on infinite-scroll feeds takes us some of the way to a causal interpretation. While the average mixture of content a user is served on their TikTok feed is undoubtedly influenced by many confounding facts about the user, the video-to-video variation in content exposure within

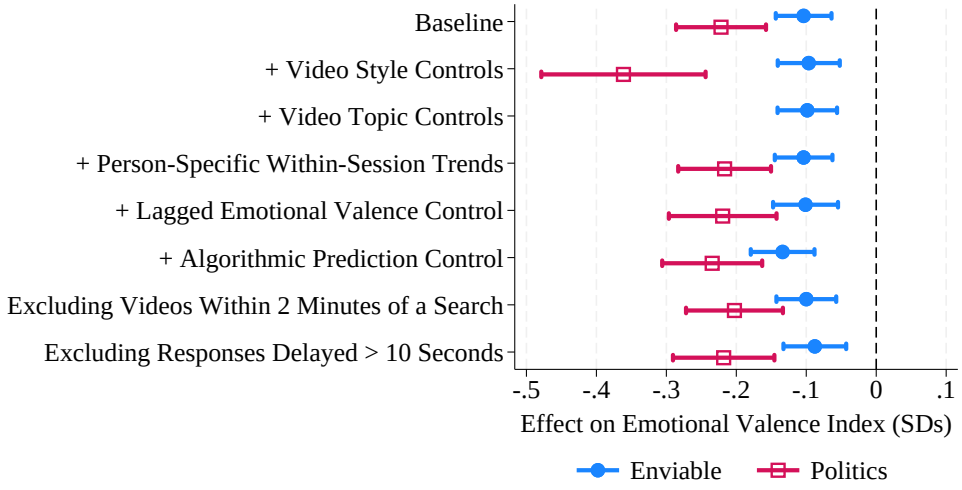

a scrolling session is likely more idiosyncratic. This is particularly plausible given the incentive for platforms to vary content unpredictably in order to take advantage of neurological features of human reward structures. As Eyal (2014) writes:

> Feedback loops are all around us, but predictable ones don't create desire... However, add some variability to the mix ... and voila, intrigue is created.

Nevertheless, a range of potential threats to identification remain. We now enumerate and attempt to address several of them.

Within-session trends. One concern is that, for independent reasons, content and emotions vary predictably within usage sessions. Perhaps, for example, enviable videos tend to be front- or back-loaded in the stream of content the platform lines up when a user opens it, and users' emotional valence tends to secularly decline or increase within usage sessions. To address this concern, Figure A63 controls for person-level within-session trends (where "time in session" is measured both using clock time and the number of videos consumed so far); adding this control barely affects our estimates.

Appendix Figure A63: *Robustness of the effects of enviable and political content on emotional valence*

Notes: This figure plots the coefficients on enviable and political content from regressions of contemporaneous emotional valence on indicators for enviable content and for our other content types (with entertainment as the omitted category). As in our standard specifications we control for session fixed effects at baseline, and then add a sequence of additional controls as described on the y-axis.

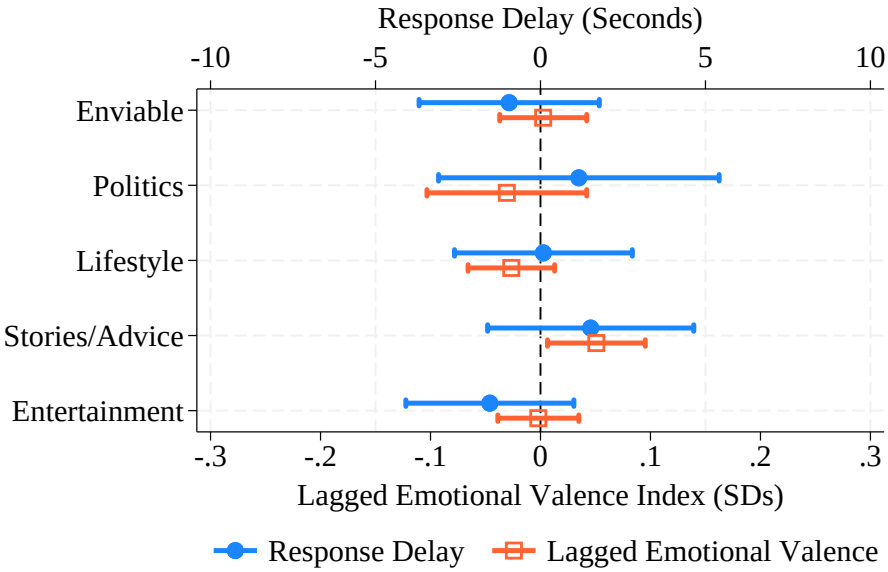

Algorithmic reactions to emotions. Another concern is that shocks to users' emotions affect the way they engage with the content on their feed, which in turn affects the future content they are served. Perhaps, for example, sad users engage more with enviable content and therefore get served more of it. We can address this concern in two ways. One is through standard tests for pre-trends: does a viewer's emotional valence *now* predict the content they see *next*? Another is by attempting to purge predictable algorithmically-driven variation in content exposure by training our own algorithm to predict the content a viewer will see next and controlling for that algorithm's prediction.

Balance tests. Figure A64 plots the results of two tests relevant to our identification strategy.

The blue coefficients test whether the type of content a viewer was watching in the second that they responded to an emotion notification predicts how long it takes them to respond to that notification. (Since we have a 99% response rate to notifications delivered while users are on social media, the extensive margin of response is not so relevant.) Zero predictiveness here is not *essential* for identification — our estimates would be biased only if the *interaction* between content viewed and contemporaneous emotional valence predicted response delays — but it is encouraging to observe. In particular, we estimate no correlation between whether the video a person is watching is enviable or political and their response delay to a notification delivered during the video.

The orange coefficients test for emotional valence pre-trends. If a person's emotional valence affects their engagement with their social media feed in a way that leads the platform's algorithm to shift the content it serves them, this would compromise our identification. Reassuringly, the orange coefficients show that the most recent emotional valence reported by a user does not predict the content they see at the time of the next notification. We perform another test of pre-trends in Figure A65.

Appendix Figure A64: *Balance tests: content on screen, response delays, and lagged emotional valence*

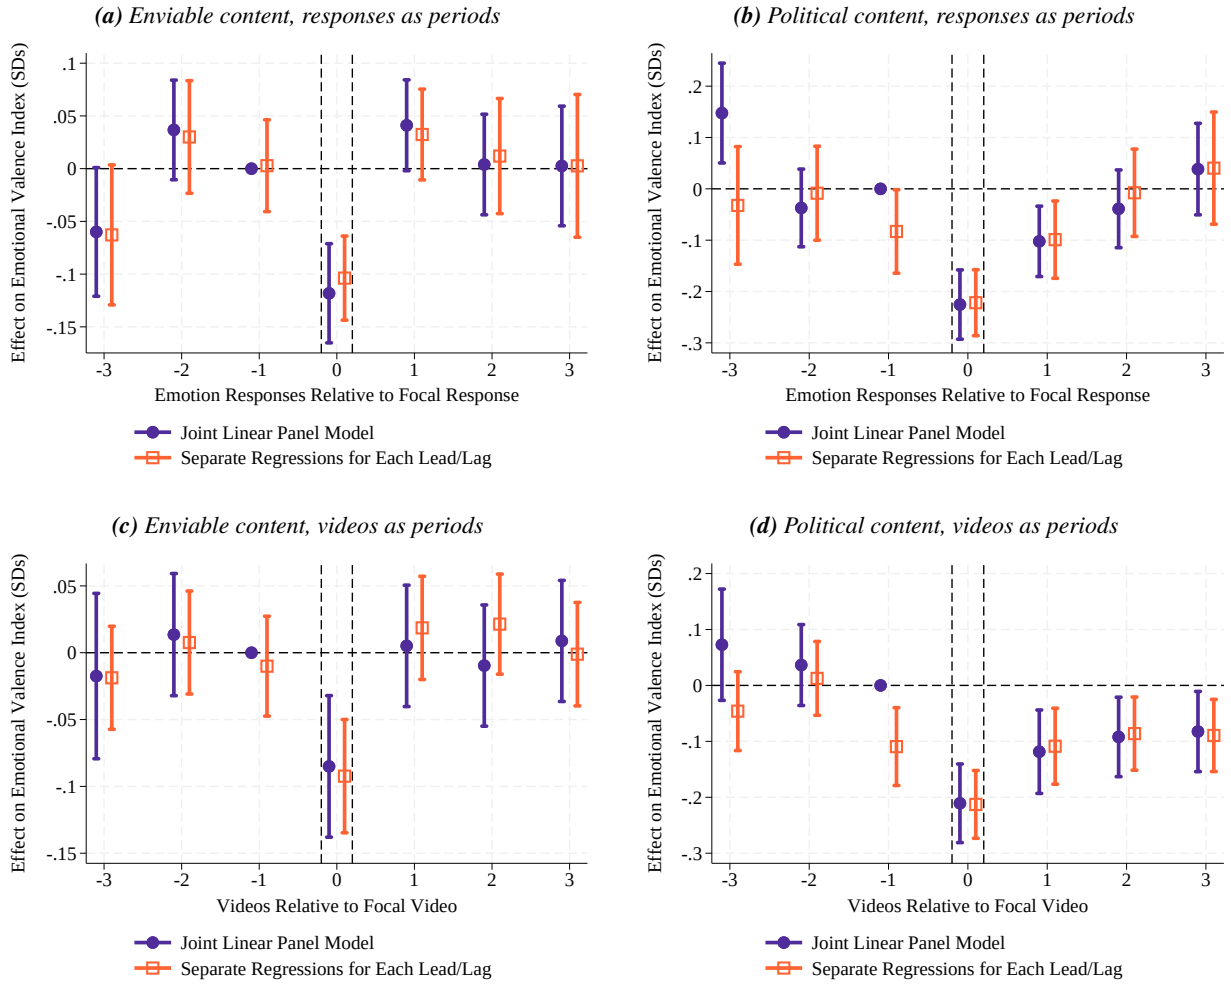

Notes: This figure restricts to videos that were being viewed at the time that a user responded to a notification from the app containing an emotion question; the blue coefficients show the correlation between the amount of time it took the user to respond to the question (top-coded at 10 minutes) and the characteristics of the content being viewed at the time of the response; the orange coefficients show the correlation of the *most recent* emotion response submitted by the respondent (within the last 30 minutes) with the characteristics of the content being viewed at the time of the response.

"Event-study" pre-trend tests. Figure A64 already ran pre-trend tests, showing that lagged emotional valence does not predict contemporaneous content characteristics. In Figure A65, we extend this through event-study-like linear panel specifications. A quirk of our setting is that, if we treat each video in the succession of videos a viewer scrolls through as a "period," we observe the outcome only in a subset of

such periods. We therefore run two versions where we define periods in different ways. Panels (a) and (b) use consecutive within-session emotion responses as periods. Their pre-coefficients therefore effectively ask whether the user's last observed emotional valence predicts the content they see now, and the "periods" are 5-8 minutes apart. Panels (c) and (d) use consecutive videos as periods, so the outcome is observed only in the periods with an emotion response. Their pre-coefficients therefore effectively ask whether the user's emotional valence now predicts the content of the video they see immediately next, and the "periods" are seconds to about a minute apart. In each panel, the purple dots run a linear panel model following Freyaldenhoven et al. (2026). The orange squares run separate regressions of emotional valence on contemporaneous content and each lead or lag of content, with session fixed effects.

We find no evidence of pre-trends except for the orange specification in Panel (d). In other words, emotional valence reacts to contemporaneous, but not future, content. Figure A63 also controls for lagged emotional valence in our baseline specification, which barely affects our baseline estimates.

Appendix Figure A65: *Effects of enviable and political content on emotional valence: linear panel models*

Notes: Panels (a) and (c) plot estimates of the effects of enviable content exposure, and Panels (b) and (d) of political content exposure, on contemporaneous emotional valence using two linear panel model specifications. The purple dots use, as a panel unit, a social media usage session, and as a time unit the nth emotion response in that session (Panels (a) and (b)) or the nth video (Panels (c) and (d)); we estimate coefficients using the package developed by Freyaldenhoven et al. (2026) and de-cumulate the $t > 0$ coefficients. The orange dots regress contemporaneous emotional valence on the characteristics of the video being viewed while the emotion response was received ($t = 0$) and, one at a time, the characteristics of the next 3 videos viewed ($t < 0$) or the previous 3 ($t > 0$), controlling for session fixed effects; in Panels (a) and (b), these are the videos being viewed at the next 3 or previous 3 emotion responses in the session.

Controlling for algorithmic prediction. Our other approach is to develop our own algorithmic prediction of the probability that a user will see an enviable video and control for this probability: that is, a propensity score adjustment. By controlling for the propensity score, we purge the predictable reactions of TikTok's algorithm to user characteristics and engagement, isolating plausibly orthogonal residual variation. Such residual variation may stem from deliberate platform randomization or simply platform uncertainty about which among many potential videos will perform best.

Recommendation algorithms like TikTok's are highly sophisticated and are sensitive commercial secrets (notwithstanding a 2021 leak to the *New York Times*; Smith, 2021), and TikTok observes more information

than we do, including whether the user likes or comments on each video (though watch time is arguably more important, given the relative rarity of likes or comments). Our objective is not to replicate this algorithm, but rather approximate this *projection* of this algorithm onto a single dimension of the latent space of videos, i.e., the dimension corresponding to enviability. To this end, we use a gradient-boosted decision tree that predicts the probability that each user will be shown an enviable video based on the user's past viewership history and past engagement length with enviable and non-enviable videos. Within each user, we use a 70%/15%/15% split for training, evaluation, and output. On the evaluation set we achieve an ROC AUC of 0.93, a PR AUC of 0.75, and a Brier score of 0.09, indicating good-to-excellent predictive performance.

As Figure A63 shows, controlling for this algorithm's prediction in our baseline specification does not affect the results, substantially bolstering our confidence that the marginal variation in content we examine is mostly idiosyncratic.

Other concerns. Figure A63 also addresses two other concerns. One concern is that participants might selectively delay responding to emotion questions while viewing certain kinds of content; Figure A64 already showed that this does not appear to be the case, and Figure A63 additionally shows robustness to the exclusion of responses that occur at least 10 seconds after notification delivery. Another is that part of the video-to-video variation in content exposure reflects users deliberately seeking out particular kinds of content; fortunately, the viewership histories allow us to observe searches, and Figure A63 shows robustness to excluding observations within the 2 minutes following a search.

J.4 Regret and demand for commitment

Panel (a) of Figure A66 shows results from two types of notifications our app delivers. One type asks respondents "what they got out of" the video they just watched, from a multi-choice list where more than one option can be selected. The first six rows plot the distribution of responses to this question, for all notifications, those delivered while the respondent is on an enviable video, and those delivered while the respondent is on a political video. Results show that enviable videos are generally rated as entertaining, funny, and visually appealing, while political videos are rated as entertaining, informative, and funny.

Another type asks respondents if they regret having watched the video they just watched and, if so, why. The final two rows of Panel (a) show that respondents regret watching enviable and political videos only in a small minority of cases.

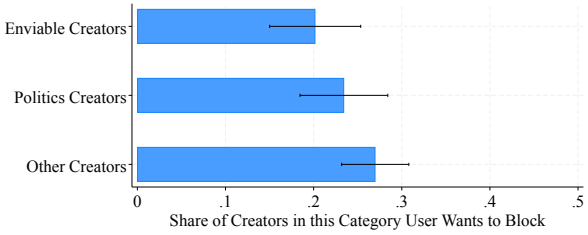

After participants submit their viewership histories, we conduct a retrospective survey where we show them a sequence of randomly selected creators from their feeds and ask if they would like the opportunity to block those creators from appearing in their feeds in future. Panel (b) of Figure A66 shows that participants say "yes" in a substantial minority of cases but are *less* likely to say yes for enviable lifestyle or political creators compared to random other creators. This is consistent with the possibility that the lifestyle and political creators that do appear in viewers' feeds are sufficiently positively selected on other dimensions to compensate for the negative emotions they trigger.

Appendix Figure A66: *Viewers do not regret consuming the political and enviable lifestyle videos appearing in their feeds*

(a) *App questions: what did you get out of the video you just watched? Did you regret watching it?*

Reason	All	Enviable	Politics
Entertaining	55%	55%	34%
Funny	32%	22%	24%
Staying Informed	22%	18%	58%
Visually Appealing	17%	23%	7%
Self-Improvement Advice	8%	13%	4%
Product Recommendation	8%	11%	3%
Regret Watching (Negative Emotions)	4%	4%	12%
Regret Watching (Waste of Time)	4%	3%	2%

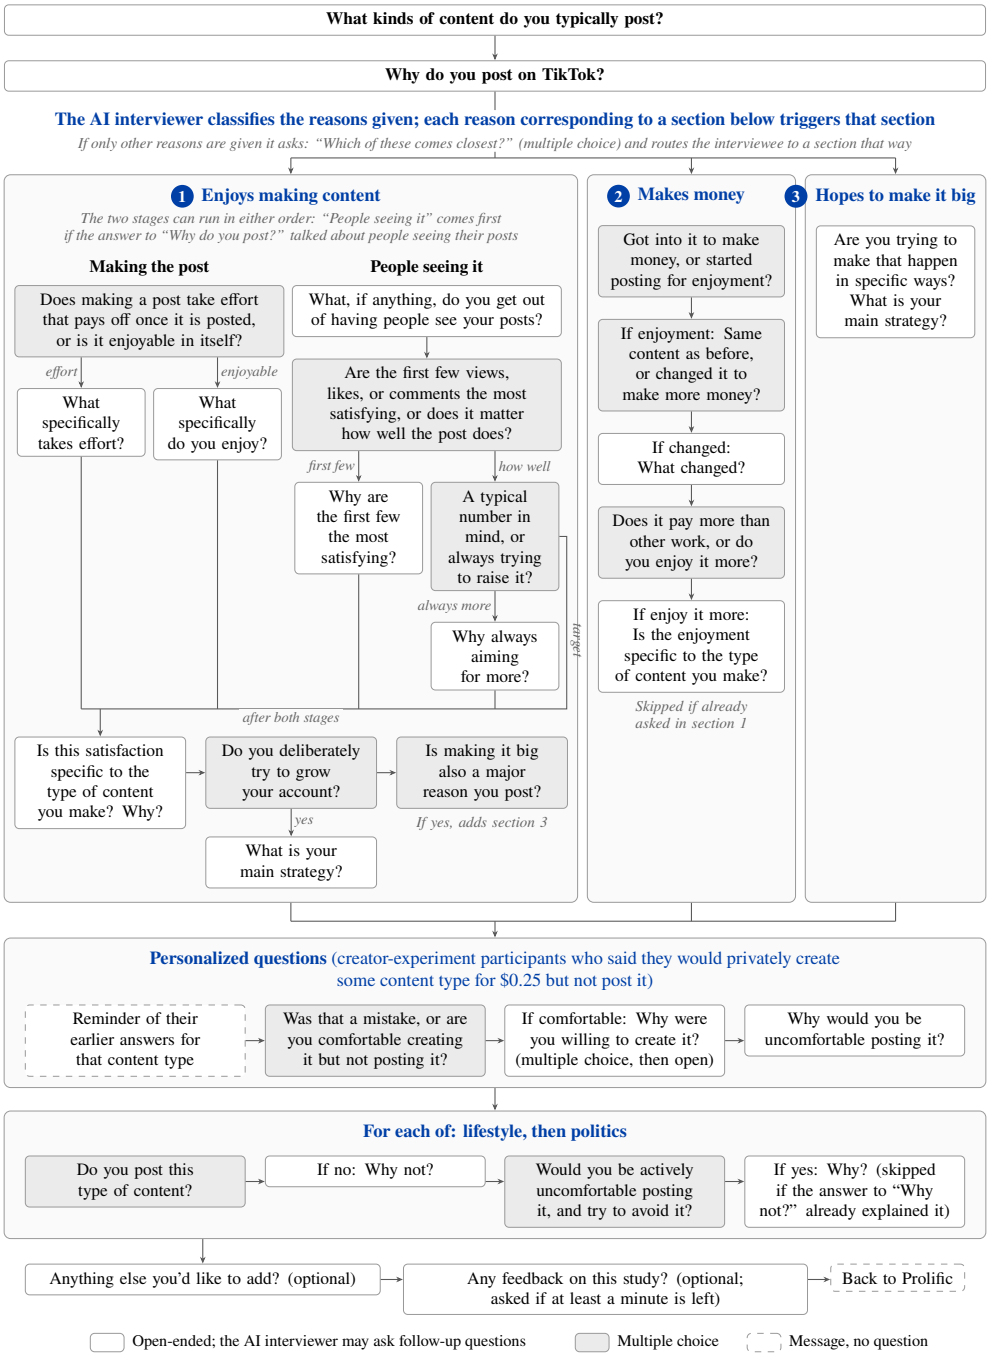

(b) *Retrospective survey: which of these specific creators from your feed would you want to block?*

K Quotes from Qualitative Interviews

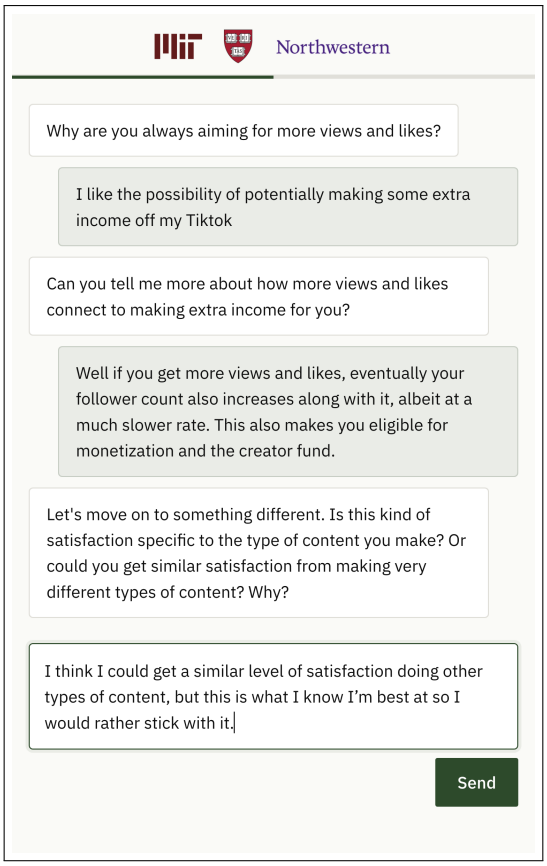

The tables below display quotes from qualitative interviews, conducted retrospectively by an AI interviewer, with participants in our user survey and creator experiment who have posted at least 3 videos on TikTok. Figure A67 shows the sequence of questions asked by the AI.

Appendix Figure A67: *Flow of the qualitative interviews*

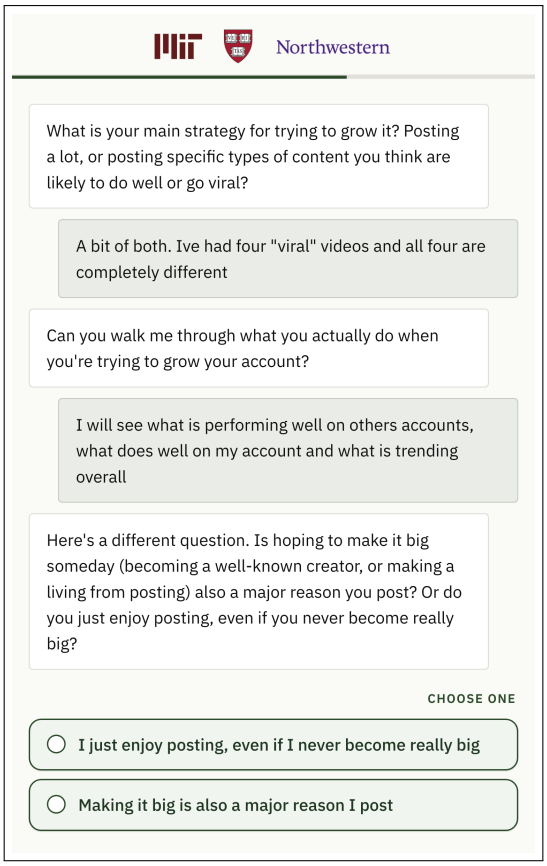

Appendix Figure A68: *Excerpts of qualitative interviews as they appear to participants*

(a) *Answering an open-ended question*

(b) *Answering a multiple-choice question*

Notes: This figure shows screenshots of the interview interface from the perspective of a participant.

Appendix Table A17: *Satisfaction from producing a video*

Making something and watching it come together	
"I enjoy the creating process of the videos and the comedy of adding specific sounds to funny videos. [...] I added a sound of "get it get it get it" over a video of my siblings dancing and it was funny [...] I thought the way the sound lined up with the movement was funny"	30
"i enjoy being able to create something for entertainment and being able to see the outcome [...] i liked being able to plan out my day and figure out what parts i wanted to film and put together in my video to be able to show the variation of events happening and then adding aethetic edits and music over lay [...] it was fun being able to create something enjoyable to watch"	120
"I like having an idea and impliementing it. It is the creative process I enjoy [...] I had an idea for a tiktok I wanted to do so I spent time filming all the parts and then edited them all together [...] I enjoyed filming the most as I got to experience the idea as I filmed. Editing can become choresome"	150

Quote	Followers
"I like editing content in a funny way and making a video look the best it can, it feels fulfilling. [...] I was editing a concert video and wanted to include some captions showing my inner feelings during a performance, and I really liked how the final product came out. [...] It felt like I was making something that my community could connect with and find great entertainment from."	320
"The post-production side [...] Synchronizing the music to combat or emotional scenes [...] Being able to fully convey the experience I curated through footage repurposing and synchronizing"	410
"I just like the creative process and the creative flow that I have when I'm creating post. It just allows me to really show my personality and in my interest in the things that I like to see other people getting engaged in their similar interest as well. [...] I enjoy putting it together the music lyrics and then also the video footage you know I tied in you know as I was watching the game and seeing the play develop you know I thought about that song and I kind of put the two together and posted it [...] It just feel natural and exciting like I'm Th e novel person I am responsible for the creation"	500
"I enjoy the process of filming and editing and seeing a good video come together that I enjoy watching, like a baking video with the finished product at the end [...] I enjoy setting up the camera to get different angles of the ingredients and the process, then taking the final shots of the baked good. I also enjoy editing and feeling like my video will be entertaining or helpful to others [...] It feels satisfying to cut the clips down and see the raw footage transform into a finished video"	650
"What I enjoy most is being able to edit the video such as the thumbnails and audio [...] I ended up changing the design and adding special effects in the thumbnail through Canva and other editing apps. What I enjoyed the most about it is being able to test out many templates."	5,200
"The editing, creation, finding the inspiration and sounds etc [...] I enjoyed the process of sourcing the footage, finding the trend and audio and the process of perfecting the hashtags and the caption [...] It was a proffessional post, so getting the caption and hashtags right was neccesary"	11,000
"The creation process and seeing the finished product. So doing the transition and editting it and seeing it come together. [...] I did a makeup transition and filming the transition was fun. I enjoyed watching the video as it developed [...] Doing the makeup itself was fun, and watching myself go from myself to made up"	16,000
Expressing themselves	
"I enjoy being able to express myself freely and display my personality [...] I enjoyed filming the angles of traveling and all the get ready with men's for the day. I really enjoy just sharing glimpses of my lifestyle [...] It's feels like producing something I am proud of"	2,500
Absorption and escape	
"it engages the creative part of my mind. for example thinking of new ideas, recording [...] i found the famous cat, and spent ages making the correct look/making it look funnier (on my face) [...] basically just focusing on anything but real life - escapism"	150

Reliving and capturing experiences	
"It is cool to put something up that I did and can look back on [...] I enjoyed trying out some new ideas about how the video could go together with the music [...] It felt satisfying"	65
"I don't really care who views my posts. I mainly use these apps as an archive or just to put it somewhere [...] I might end up losing it or breaking the device containing the original footage [...] It was ok, I always like to appreciate others but sometimes I feel like I like my solitude [...] Felt like someone viewed something that I did."	65
"It is fun making videos to look back on as memories"	210
"I enjoy making travel releted content, which I share about my travel journey. when I making it I can relive with it [...] I post some pictures of trip I took in [a region]. I add notes about my experiences with each photos. My view about places I visit, my opinion about food I had [...] I felt the excitement that I had when I am experiencing those moments. Then , after post it many people had similar experiences"	260
"I do it for myself anyway. I maintain it as my memorey book. I can log in to it in future and can enjoy it. I don't have large follower base anyway. [...] It make me happy little bit and feel like small accomplishment [...] I put some effort to create it. So, when someone enjoy it or use it, its give me joy"	260
"I love trying the trends that go around on booktok , for example "books that define my reading taste" [...] Putting all the pictures of the book covers on the post as it reminds me of how many books I really have read and absolutely loved! [...] That I'm just immersed in a world of books and fictional stories and it really relaxes me!"	1,500
"I post to document my life and also interact with viewers"	2,500
Looking and feeling good	
"Creating something that I can share with others [...] Feeling sassy and hot gave me empowerment [...] Just looked cute and lip synced to a song I like"	39
"I just like looking good and I like when people agree [...] Cause I looked so good that day just did my hair and also it was my birthday [...] Just getting dressed up"	99

Notes: This table shows answers to "What specifically do you enjoy about making a post? Please be specific and give some examples." Quotes are verbatim and "[...]" indicates places where the AI interviewer asked a follow-up question; answers to successive follow-ups are joined into one quote.

Appendix Table A18: *Satisfaction from having people see one's posts*

Quote	Followers
I don't care about this	
"nothing [...] i didn't really consider others when i posted [...] a reality tv stars husband responded to my comment with a video [...] it was pretty cool. i started thinking about the six degrees of separation"	24

(continued)

Quote	Followers
"I don't really care who views my posts. I mainly use these apps as an archive or just to put it somewhere [...] I might end up losing it or breaking the device containing the original footage [...] It was ok, I always like to appreciate others but sometimes I feel like I like my solitude [...] Felt like someone viewed something that I did."	65
"i don't really pay much attention to who sees my post, i post for fun not views [...] it's nice to see someone like or interact with the fun videos [...] nice that someone enjoyed the video as much as me"	120
"I don't really get anything from it. I do enjoy the occasional compliment. However, I mainly enjoy going back and watching them myself. [...] I enjoyed how it made me feel [...] It made me feel happy and appreciated."	150
"nothing [...] same as it was before i posted it. makes no difference to me [...] it doesn't effect me"	540
Connection and small-scale, two-way interaction	
"I want to be a gamer content creator online so it's nice to bring the gaming community together [...] I don't have a lot of gamer friends so I'm trying to be more in the community [...] Enjoyment. I was happy that people had fun with my content [...] Their responses were positive and engaging"	25
"not much just a small bit of connection [...] a like or a comment made me feel connected to the viewer [...] I got one just hyping up the video it made me feel happy"	30
"I get a community that likes the same things I like [...] People who finds what I post funny and are ready for more post from me [...] It was fun because I got to see so many people happy about it"	43
"I don't get much out of anything. Just more followers and likes. I don't care about those things but just putting something out someone could relate to, and maybe become mutuals. [...] Friendship [...] Having someone that has something in common with you. Having someone you could talk to about things only you understand is cool. [...] Honestly, the ice video. A girl commented and said she loves chewing ice too. She followed me, I followed her back, and we instantly connected and started chatting."	54
"make new friends [...] they found my post funny or relatable and we would meet based on those interests [...] it makes me feel happy because it's like people like me"	150
"I am able to interact with others in the comments section, either feeling happy when they express that I helped them or sometimes they offer me advice too that helps me for the future [...] I posted a video learning how to use a sewing machine and someone commented with a lot of good tips and advice for how to better use it to it's fullest possibilities [...] It felt good and I was happy they chose to take the time to share that with me"	650
"I meet new people! [...] Really nice, I like talking to people about what books that they like and therefore we give eachother some book recommendations! [...] That I can have a conversation with someone about something I love and that I am so passionate about as a lot of my family and friends don't understand why people love to read!"	1,500

(continued)

Quote	Followers
"I get to interact with individuals that see my post which builds a little community. [...] Someone made a funny comment reply to my post and it was hilarious [...] It was just a little laugh to brighten my day and I gained a potential consistent viewer"	2,500
Pride or general validation for making a video people liked	
"i do not get much out of it, but it is nice to watch my likes rise [...] it was really exciting honestly [...] seeing the numbers go up and watching my phone blow up wiht likes"	150
"I get validation that people enjoy my videod [...] I posted a horror tiktok showing clivps and a montage from a film i like it it got alot of views and nice comnent [...] It made me feel comfortable [...] It made me proud that other people like my videos"	170
"I do it for myself anyway. I maintain it as my memorey book. I can log in to it in future and can enjoy it. I don't have large follower base anyway. [...] It make me happy little bit and feel like small accomplishment [...] I put some effort to create it. So, when someone enjoy it or use it, its give me joy"	260
"I get recognition from a wide audience and it feels good seeing people like my content. [...] Recently I had a video go viral with over half a million views and over 150,000 likes! That was a huge milestone for me because it was my most viewed video by far. I felt super proud that people liked it and found me funny."	320
"Just self satisfaction Observing the increase of view and likes would also offer an validation to myself [...] Very satisfying to watch [...] Observing the increase of view and likes would also offer an validation to myself [...] It shows that this video is a piece that the public like to watch and want more of it Which is created by myself"	340
"it is nice seeing when you get a larger amount of views than normal, but i just enjoy sharing certain fun things or whatever that im doing [...] it was a year ago during [a hurricane], i posted a crazy video and it got a lot of views (for me) and it was pretty exciting! [...] i just dont get many views so it was cool to see that my post reached such a large amount of people [...] kinda because it was about a current event and because the intensity of the video"	450
"Pride and satishfaction [...] A lot of people hearted it and commented how cute my rats were and I was so happy to share my joy with others"	1,100
"I mean I obviously like getting big on tiktok like getting a bunch of likes is the best part for sure [...] it makes me pretty happy because im like wow they really think im funny"	1,500
Pride or validation for abilities shown in a video	
"No, there is no need for that [...] I do need to get out to have people see my content [...] Sorry I misunderstood the question! I dont get anything out of my content. Mostly are joy to share my car [...] That people would comment and like my posts and appreciating what I have or what I have modded on my car"	34

(continued)

Quote	Followers
"It boosts my self confidence and confidence in what I offer, and motivates me to keep going and move forward. [...] Yes, when I posted a clip of my gameplay, there was a comment saying that I am a talented person. [...] I felt proud."	540
"I feel good knowing my creativity is seen [...] Its a feeling of success and pride, because ive spent a long time developing my skills and my creative side"	16,000
Appearance-related social validation	
"Nothing just a confirmation that I look good [...] Yess by commenting [...] Hearts eyes [...] Nothing really I'm use to comments like that"	99
"liking, commenting and giving compliments or asking what products, clothing I might be wearing and being able to be positive and friendly to others [...] I feel like I am giving them assistance and acknowledging their question [...] I felt good because they seemed to like what I was wearing and they could go out and purchase it themself"	210
Making a difference to viewers	
"I get some sort of satisfaction from the fact that i could have possibly inspired them and entertained them, it makes mee happy and feel like ive done a good job [...] Yes, once a viewer said they loved my reaction to getting a kill on call of duty and it really made me feel happy that im enteratining my viewers"	530
"I want them to be able to have good feelings or have the song take them back to a specific time where their life was something that the reminisce about [...] It makes me feel good [...] They dont even have to comment i appreciate a like or even a share or save [...] It means my post made that viewer feel something good"	1,300
"i get a sense of pride and satisfaction from my peers relating and consuming my content [...] yes, i have multiple post that i made during the early stages of my pregnancy that included product reviews about items that i received from medicaid for example and gave insight on how to obtain the different services and items and that helped one young lady specifically outgain a carseat as she couldnt afford it on her own and that made me feel so proud"	1,400

Notes: This table shows answers to "What, if anything, do you get out of having people see your posts? Please be specific." Quotes are verbatim and "[...]" indicates places where the AI interviewer asked a follow-up question; answers to successive follow-ups are joined into one quote.

Appendix Table A19: *Reasons for concave returns to attention*

Quote	Followers
Small-scale, two-way interaction	
"I don't get much out of anything. Just more followers and likes. I don't care about those things but just putting something out someone could relate to, and maybe become mutuals. [...] Friendship [...] Having someone that has something in common with you. Having someone you could talk to about things only you understand is cool. [...] Honestly, the ice video. A girl commented and said she loves chewing ice too. She followed me, I followed her back, and we instantly connected and started chatting."	54
"make new friends [...] they found my post funny or relatable and we would meet based on those interests [...] it makes me feel happy because it's like people like me"	150
"finding likeminded people with similar interests [...] I found other people who like crochet and we talked about our projects and shared tips with one another [...] I find it enjoyable and helpful [...] I learnt quite a lot about different crochet styles and how to do certain techniques"	1,400
"I meet new people! [...] Really nice, I like talking to people about what books that they like and therefore we give eachother some book recommendations! [...] That I can have a conversation with someone about something I love and that I am so passionate about as a lot of my family and friends don't understand why people love to read!"	1,500
"its exciting seeing your friends interacting with your content [...] it was so much fun we were just bantering and laughing in the comments section [...] its just how we used to interact back in school also its very hilarious [...] My friend was telling me to remember a time when we swore we would be body built and maintain abs even as adults"	1,800
"I get to interact with individuals that see my post which builds a little community. [...] Someone made a funny comment reply to my post and it was hilarious [...] It was just a little laugh to brighten my day and I gained a potential consistent viewer"	2,500
"I have the ability to be able to interact with my followers and join their live streams [...] A recent time I interacted with a follower was when they mentioned me in their story and after that happened. Me and them been playing games together and streaming anime [...] It was a peaceful experience because the person was friendly and caring [...] What made it rewarding was the friendship I gained from that experience"	5,200
"The positivity and good vibes, a wholesome community in which we can discuss what we share interests in. [...] They commented and helped each other relate to a difficult part of a game I was playing, it was very close connected. [...] A sense of joy that people could relate to one another."	5,600
"I have people who regularly watch my content so I get joy in seeing how they react and comment to my videos [...] Me and my wife recently posted an image trend showing all the places we've traveled together and it got a lot of comments from people who wish to have similar travel experiences one day. [...] It made me feel happy that I was able to share my travel experiences with my fans"	70,000
Early viewers matter more than later ones	
"because the first comments and likes shows that the person cared to do it [...] boring"	57

(continued)

Quote	Followers
"posting often with consistency so I can build a following that actually enjoys my videos instead of quick viral hits"	650
"i usually just pay attention to those the most cause thats like the real reach, after that its just people going on my profile to spam me and not liking or commenting because they first saw it and liked it [...] commenting and liking every post [...] it does not feel genuine"	1,400
"I think the first views, likes, and comments are usually from my friends and the people I'm closer to, so I value their comments a lot more than comments from people randomly stumbling across my content. [...] Sometimes I make videos that I'm scared will anger people I'm close to, like where I'm discussing a hot take or an unpopular opinion. I feel satisfied when these people actually agree with what I'm saying, and can see my perspective and where I'm coming from."	17,000
"Just seeing that people saw it at all and wanted to leave behind a comment right at the beginning shows me that people are genuinely interested. Of course, the more views it gets the more satisfying as well, but those first few people matter the most because they were the ones who saw it before the video might have gone viral [...] The first few comments always seem to be more interested and put more effort into showing how they feel about the video and leaving behind comments that are more thoughtful. Later comments tend to just be random things that don't matter as much or not much thought was put into them, more of a casual reaction than an actual thoughtful comment"	35,000
Paying attention only shortly after posting	
"because im usually only focused on the views or comments right after I post [...] I was paying attention to who viewed and liked the post [...] I typically lose interest and forget to go back and check because many of my posts dont get many views"	30
"The first few views means the people who initially saw the video liked it and it appealed to them, later on I would have moved past the fact that I posted and no longer care"	39
"Because I often forget that about what I posted much later after the fact and If I see the post isn't doing well in the beginning, I assume it won't do well [...] If I am not getting many views [...] The last time I posted I saw the view count continuously rising at a steady pace so I was happy to see that it was reaching people"	150
"It's the instant gratification, you dont have to wait [...] it was cool to see how fast other people see the stuff i post [...] it gets old fast, i normally am focused on something else as time goes on"	1,100
"Because I'm usually on the app in that moment, when I first post. So, seeing those first views and likes and comments make me happy to engage with others. I usually won't look at the post again for a couple days [...] I usually notice the views or likes first. [...] It usually will feel either worse or good, depending on how well the video does."	1,200
"Because it feels somewhat engaging. I don't normally care how well a post does. [...] I just turned my attention to other things. [...] It feels somewhat exciting but nothing else really."	1,400

(continued)

Quote	Followers
Knowing that at least some people saw and liked it	
"That at least a handful of people connected with my content. The rest are like extra credit [...] It looks like views. Comments and likes are nice too [...] Gratifying"	51
"It means people is actually seeing the post and is engaging [...] That it was avery popular song that had everyone feeling good"	1,300
"I feel like the first few views, likes, or comments are the most satisfying because it often dictates how the post is going to do in general, whereas the later views and likes are expected because it just follows a general trend/curve. I tend to actually put my phone away and not care about the first few reactions, because it's scary and I could feel dejected/rejected if it doesn't do as well as I am hoping [...] It depends, but usually I try to come back with no expectations, so it is always nice seeing some reactions rather than no reactions at all."	5,200
"Because I already know people have seen my video [...] The excitement of posting it was gone [...] I get a rush from hitting post"	6,200
"I have a big following so I know I'll get some view regardless, but it's nice to know that there are people who still care [...] They see it quickly and like and comment [...] I'm still appreciative of any engagement I get on my posts"	41,000

Notes: This table shows answers to "What, if anything, do you get out of having people see your posts? Please be specific" (first group) and "Why are the first few views, likes, or comments the most satisfying? What makes later views and likes less important?" (other groups, except for one answer to "What is your main strategy for trying to grow it?"). Quotes are verbatim and "[...]" indicates places where the AI interviewer asked a follow-up question; answers to successive follow-ups are joined into one quote.

Appendix Table A20: *Is the satisfaction specific to the content one makes?*

Quote	Followers
Yes: specific to the content I make	
"No, it's different when I post about experiences it's more a shared satisfaction from people who have the same interests or went to the same event appreciate the post"	39
"It's typically what I post because it's my own interest I wouldn't post anything I don't find interesting [...] Yes [...] Just trying new things out"	43
"It's more satisfying cause I actually enjoy gaming [...] It's something I like so it seems less like an effort"	91
"I could get this with any content as long as it is regarding an topic i like [...] Movies"	170
"I feel like if it was different content but still something I was interested in I would still feel good because im there helping people"	210
"It dependes. I already enjoy travelling eventhough I make it content or not. I don't like to make joke video, I may not feel the same with making those kinds of contents. However, there can be other interest I prefer to make it as a conten"	260

(continued)

Quote	Followers
"Good question but I believe it's only on the specific type I made [...] Because it is something I genuinely like to explore and want to share"	340
"it's specific to the content because that's what i enjoy doing"	540
"I am not sure, I think it wouldn't feel the same because the content I make now feels like me and different content that doesn't feel like me probably wouldn't feel satisfying to get interactions from"	650
"I think its more related to the specific content that i make because i mainly make content that is aimed at helping people or informing people and thats where i get that satisfaction in return."	1,400
"I think all types of content could get similar satisfaction, but mine might be differnet because its comedy [...] because its validation on something that is innate like you cant train humor i think"	1,500
"I get satisfaction from all my content because it is something I made and created from my own brain [...] If it was still something relevant to me or my life i would always feel satisfaction. [...] Anything political, mental health and neurodivergence and other stigmatised topics"	16,000
No: similar satisfaction from other content	
"I get satisfaction making different types of content too because content making and sharing is fun [...] I would make GIFs to post on blogs and the internet because I think people enjoy looking at them"	25
"Yes I can get a similar satisfaction by posting something funny and getting reactions"	99
"i would get it for any content. its just fun to see people relating to it"	150
"I think I could get a similar level of satisfaction doing other types of content, but this is what I know I'm best at so I would rather stick with it."	320
"Any form of content, as long as I enjoy the creative process [...] It must be both challenging and exciting [...] A project that puts your creative abilities to the test, attempting techniques and styles you wouldn't usually do"	410
"I could probably get similar satisfaction from making other content as I love watching TikTok videos and I spend a lot of time on TikTok and I get inspired from other peoples posts!"	1,500
"I like the process of creating content in general therefore, no matter what the content I think I would enjoy it"	11,000

Notes: This table shows answers to "Is this kind of satisfaction specific to the type of content you make? Or could you get similar satisfaction from making very different types of content? Why?" Quotes are verbatim and "[...]" indicates places where the AI interviewer asked a follow-up question; answers to successive follow-ups are joined into one quote.

Appendix Table A21: *Strategies for growing one's account*

Quote	Followers
I don't deliberately grow my account	
"wait no i dont deliberately try to [...] ill sometiems try to boost it or something or share it or repost so i get more engagement [...] i repost it to other platforms"	1,500
Through posting volume or general production quality	
"Posting frequently at the right time with the right hashtags [...] I look online for analytics [...] I search how to post at the right time and listen to other popular content creators' advice"	25
"Posting a lot and being consistent [...] Posting everyday at the same time"	43
"posting everyday [...] i just make drafts [...] i recorded videos"	150
"Posting semi-consistent quality media [...] Polished the project as well as my technical skills [...] Instead of intense effects, I refined the experience through more intentional choices"	410
"posting often with consistency so I can build a following that actually enjoys my videos instead of quick viral hits"	650
Through posting specific content types I think will do well	
"Posting specific types of content that I think will do well! [...] Because I have seen it all over booktok and I seen that it went viral so I wanted to try it too! [...] The ones that I think fit well with my account or ones that I enjoy watching so therefore I hope the people who view my posts will also enjoy watching!"	1,500
"My main strategy is to post new videos once every week. I mainly post anime and gaming content because it is more likely to go viral."	5,200
"posting consistently and frequently [...] usually a few posts per day occasionally I get slack and post less, but generally I try to stay consistent [...] Depending on the account, it depends on what viral trends I have seen or what content seems to be performing well"	11,000
"A bit of both. Ive had four "viral" videos and all four are completely different [...] I will see what is performing well on others accounts, what does well on my account and what is trending overall"	16,000

Notes: This table shows answers to "What is your main strategy for trying to grow it? Posting a lot, or posting specific types of content you think are likely to do well or go viral?" Quotes are verbatim and "[...]" indicates places where the AI interviewer asked a follow-up question; answers to successive follow-ups are joined into one quote.

Appendix Table A22: *Why participants don't post lifestyle content*

Quote	Followers
Privacy and anonymity	
"I don't want to share my face or personal information on the internet"	25
"I prefer to keep anonymous on social media platform [...] like i don't like putting myself on camera"	56
"I like my privacy, feels to invasive to my life"	1,100

(continued)

Quote	Followers
My life isn't interesting or aesthetic enough	
"I dont find my life very interesting or aesthetic [...] It is just typically. I live in an older home in a small town. No fancy clothes or fancy activities. Just normal adult stuff going to work and coming home"	30
"i don't think my life is aesthetic enough [...] it's not "camera worthy" i don't do anything on the day to day that would be interesting to record"	150
"i dont have an exciting life [...] all i do is work [...] i would be giving away personal infromation"	150

Notes: This table shows answers to "Why not?" from participants who said they do not post Life Highlights content (aesthetic or interesting casual moments, activities, belongings, surroundings, or features from one's own life). Quotes are verbatim and "[...]" indicates places where the AI interviewer asked a follow-up question; answers to successive follow-ups are joined into one quote.

Appendix Table A23: *Why participants don't post political content*

Quote	Ideology	Followers
Avoiding arguments, conflict and abuse		
"I dont feel strongly politacally and do not want to fight with people online about it"	Slightly conservative	30
"don't care for the argument [...] politics makes people argue"	Moderate	120
"i don't want to have arguments about politics. i have my views and i don't really care about what other people think of them"	Liberal	150
"I dont like posting about politics as everyone has their own opinions and it can cause a lot of judgement and arguments online"	Moderate	210
"I don't like getting into politics as I feel like it can be very controversial [...] Everyone has a different option and if you aren't on their side then it can cause a bit of tension!"	Conservative	1,500
"Too much arguing around that topic [...] I'm not real political myself and I don't want the confrontation around it"	Moderate	9,800
"I find politics a very negative topic. Its very polarising in the current climate. I posted one video and was met with a barrage of abuse so it is not even worth the mental strain"	Liberal	16,000
Not interested or not knowledgeable enough		
"I don't care about politics"	Liberal	25
"I'm not really into politics."	Moderate	54
"I just don't want to share my political opinions as I'm not an expert"	Liberal	63
"I don't have very strong political opinions nor would I like to push them upon others"	–	65
"I dont really understand politics i dont get involved in it"	Moderate	170

Quote	Ideology	Followers
Keeping politics private or off my page		
"I don't want my page to be associated with politics"	Liberal	650
"In my lifestyle vlogs I may post myself going to vote but I don't ever state my stance because I don't care to open my platform up for debate regarding politics or important topics. I have my views and May state them but it isn't a platform for me to want people to say their views. My content is my life so I only care to show that"	Slightly liberal	2,500
Worried about future employers		
"im trying to get a job iin the future [...] if you post something that employers don't agree with youre cooked"	Moderate	1,500

Notes: This table shows answers to "Why not?" from participants who said they do not post Political Opinions and Discussion content (an opinion, observation, or useful information about politics or current events). Quotes are verbatim and "[...]" indicates places where the AI interviewer asked a follow-up question; answers to successive follow-ups are joined into one quote.
